semilunar cartilage may be removed entire or left in situ. The lateral pouch of the joint is freed of synovial membrane up to the border of the patella, and the lateral aspect of the femoral condyle is also cleared. While the operator holds to this mass of synovial membrane, the suprapatellar pouch is carefully freed of its synovial lining, and the dissection comes over the femur to the mesial pouch of the joint. The internal semilunar cartilage may be removed or left in place. The removal ends with the inner half of the infrapatellar fat pad. The space between the femoral condyles and the two crucial ligaments is now cleared of synovial membrane.

5. The margins of the articular cartilages where pannus growth has established itself are wiped clean with gauze, more or less damaged cartilage being exposed.

Fig. 7.—Two instances of involvement of the knee joint in which synovectomy was performed. The knees are swollen, boggy and painful on motion. There is marked thickening of the synovial membrane, sometimes described as "atrophic arthritis," "rheumatoid arthritis" or "chronic infectious arthritis." In each instance synovectomy was done, with entire relief from symptoms and with good return of function. The section of the synovial membrane revealed the characteristic picture of proliferative arthritis (see fig. 4).

The entire joint cavity is carefully wiped with gauze to remove loose vestiges of synovial membrane.

6. The knee is closed by interrupted suture of the quadriceps and patellar tendon and the capsule about the margin of the patella. We have habitually used no. 2 chromatized catgut. The subcutaneous tissues are approximated by interrupted sutures of no. 1 plain catgut. The skin is closed with silk or dermal continuous stitch. A firm dressing and bandage are applied, and the tourniquet is removed.

7. The knee should be kept at rest for from twenty-four to forty-eight hours and supported in suspension slings. The patient should be encouraged to move the joint. Active motion should be encouraged early but never passive motion of any kind. A Thomas splint with Peirson attachment is a convenient form of support.

8. Until the healing of the skin wound is complete and the stitches are removed, nothing strenuous in the way of exercise should be used, except daily exercises for

the quadriceps extensor. The patient should be taught and encouraged in the setting of the quadriceps femoris muscle, and should perform the exercise many times each day. As soon as the wound is healed, the patient should be up in a wheelchair, should have crutches, and should make as much progress each day toward movement of the joint and weight bearing as is possible. Pain should be avoided. We have found that most of our patients regain considerable motion within three weeks. In several instances when there was delay at early movement, we have found it necessary later to flex the knee gently under an anesthetic.

9. After-care consists of heat, massage and exercise. Functional use should be attempted as soon and as much as possible.

10. Our experience justifies the recommendation that at the time of synovectomy the semilunar cartilages be removed.

Long since we have given up the use of plaster-of-Paris and all forms of stiff splints.

Fig. 8.—After-treatment in synovectomy. Use of the Thomas splint with Peirson attachment. The extremity is suspended so that its weight is counter-balanced. The patient has control of the Peirson attachment with the weight which is in her hand. Early motion of the joint which has been operated on may be encouraged.

#### SYNOVECTOMY OF OTHER JOINTS

In several instances of chronic multiple arthritis, synovectomies have been performed on other articulations. The wrist joint is often affected and offers a suitable field for synovial removal.

It seems feasible to recommend synovectomy in the proliferative type of arthritis as soon and as extensively as possible. The marked improvement in general well-being and in symptoms both in the joint operated on and in other joints seems to indicate definitely that the synovial membrane bears more than a secondary relationship to the disturbance in the joint. Indeed, we are inclined to believe that this type of arthritis is primarily a synovial disease. Furthermore, once established in the synovial membrane, it has, as Swett has suggested, the potency of an original focus of toxic or bacterial influence on the other articulations.

## CONTRAINDICATIONS TO SYNOVECTOMY

It seems to us that there are few contraindications to the removal of the synovial membrane in the chronic proliferative type of arthritis. Pain and discomfort are greatly relieved; functions are improved, and the patient usually shows marked improvement in the other joints which are involved. Therefore, age, general physical condition, hopeless inactivity, etc., are not contraindications. We have operated on several persons who had been bedridden and chairridden for years, whose general health was below par and who seemed to present every reason for nonintervention. We found that they tolerated the operation well, improved in every way and were finally able to walk.

Fig. 9.—After-treatment in synovectomy. Method of suspending the extremity after synovectomy. The supporting slings are made of saddle felt, and the weight of the extremity is counterbalanced so that the patient may move the knee joint.

Joints affected with acute pyogenesis and acute gonorrhea should not be synovectomized; ankylosis is perhaps hastened.

The tuberculous joint should not be synovectomized alone; synovectomy in conjunction with bony fusion is indicated in tuberculosis of the joints.

Joints affected with chronic quiescent gonorrhea recover good function without pain or disability after synovectomy.

Our experience with synovectomy has been as follows: From October, 1923, to October, 1928, fifty synovectomies have been done in the Orthopaedic Service of the Massachusetts General Hospital. In practically all of the cases the same operative technic was used, which consisted of a paramesial patellar incision, dislocation and retraction of

the patella outward, with complete removal of the synovia. The best exposure is obtained with the knee completely flexed. In four recent cases, both semilunar cartilages were removed. The general routine of after-treatment has been to start active motion on the second or third day, the knee being suspended in balanced slings or a Thomas splint with Peirson attachment. Weight-bearing was usually allowed at the end of a week to ten days with crutches, and in a few instances weight-bearing was begun on the fifth day after operation. The guide to the extent of motion to be encouraged as well as the time to allow weight-bearing is the presence of pain and discomfort. We have cautioned these patients to avoid movement or attempted function which causes pain in the joint.

Double synovectomies were performed in three cases; that is, the synovial membrane was removed from both knees at separate operations, several months apart.

#### *Diagnosis in Fifty Cases*

---

Chronic infectious arthritis . . . . .	27 (of this number 19 had multiple involvement of the joints, 8 were non-articular)
Gonorrheal arthritis . . . . .	4
Tuberculous arthritis . . . . .	6
Hypertrophic arthritis . . . . .	5
Osteochondritis dissecans . . . . .	2
Charcot joint . . . . .	1
Giant cell tumor . . . . .	1
Internal derangement . . . . .	1 (with hypertrophy of the synovia)
Atrophic or so called hypertrophic villous arthritis . . . . .	3
Three patients died of other diseases after leaving the hospital	
In five cases, the patients could not be traced	
Forty two cases were available for studies of end results	

---

The fifty cases were subdivided as to diagnosis, as shown in the accompanying table.

It is interesting to note that there was one case classified before operation as chronic infectious arthritis in which microscopic sections and inoculation into guinea-pigs showed the presence of tuberculosis

One patient died of sepsis following operation.

Three cases resulted in fusion of the knee joint

There were four cases of gonorrheal arthritis of the knee in which synovectomy was done; two of these resulted in fusion; the result in one was unknown, and the fourth showed 90 degrees painless function and complete extension one year following operation.

There were four cases of tuberculosis of the knee, in all of which synovectomy was done as a preliminary step to operative fusion.

Three cases of the chronic infectious arthritis ended in fusion with painless weight-bearing function.

In this series there were eighteen males and thirty-two females; the youngest patient was 15 and the oldest 65 years.

A study of the cases showed that more than 95 per cent of the patients were relieved of pain by the operation. In only two cases was there a recurrence of pain: in the first, this occurred three months following operation; in the second, almost a year elapsed after operation before the reappearance of pain.

It was found that the average motion following operation was about equal to or slightly less than that present before operation. If there was flexion of 90 degrees, the result was found to be satisfactory from the patient's point of view. In patients with less than 90 degrees of flexion, some difficulty was experienced in going up and down stairs.

In the whole series, the average period of time before return to work (part time) was six months, and from ten months to one year for full-time work. More than 75 per cent were able to go back to their original work; five patients who had been complete economic losses for

Fig. 10.—Synovectomy performed on the right knee. Range of motion accomplished without difficulty by the patient three weeks after operation.

from one to one and a half years prior to operation returned to their original occupation after operation.

From the patient's point of view, the results were satisfactory in all but three cases: two of these patients stated that their knees were no better than before the operation; one patient stated that he was worse than before the operation. Following operation, one of the patients had relief from pain lasting about three months. In a fourth case relief from pain lasted one year, when a recurrence of all the original symptoms developed, and it was necessary to do a second synovectomy; at the second operation, it was found that there had been a complete regeneration of the synovia. The appearance at operation was much the same as at the time of the first operation. There can be little doubt of the fact that synovia regenerates. Until the work of Key and Wolcott,<sup>14</sup>

14. Key, A.: *J. Bone & Joint Surg.* 7:793, 1925. Wolcott: *J. Bone & Joint Surg.* 9:67, 1927.

there was some doubt about the manner in which this regeneration occurred. Key, working with dogs, showed decisively that this regeneration occurs from metaplasia of the connective tissue cells, and that it is possible in the dog for the complete restoration of a normal appearing and functioning synovia.

In the multiple infectious arthritis group in which both knees were affected and one knee only was operated on, all the patients but one stated that the knee operated on was less painful than the knee not operated on. This one case was classified as an unsatisfactory result, and later came to operative fusion.

It is difficult to estimate the effect on the patient's general condition. From a study of these cases, more than 65 per cent of the patients reported improvement in their general condition; whether this was due to actual removal of the source of infection or of the improved physical function of the patient as a result of exercise and freedom from pain it is difficult to estimate, since many cases of arthritis show periods of improvement.

From the surgeon's point of view, the operation seems to be satisfactory. Ninety per cent or more of the patients are relieved of pain, and a great many who had been incapacitated before operation are able to return to work. Function in the joint is not decreased. Alinement and weight-bearing are usually improved.

From a study of these cases, one has a right to expect at least as much motion after operation as was present before operation; 90 per cent showed as much motion as before operation; 5 per cent showed gain, and 5 per cent loss. It is interesting to note that in the small series of four cases of gonorrheal arthritis, 50 per cent resulted in fusion, and pain was not relieved in any case.

From a limited series (four cases), removal of both semilunar cartilages seems to improve the comfort and function of the knee after operation.

#### SUMMARY AND CONCLUSIONS

1. Synovectomy is a useful operation in properly selected cases in polyarticular as well as in monarticular arthritis.

2. In practically all cases, it relieves pain and enables the patient to resume weight-bearing.

3. Of the series here reported, 65 per cent showed marked improvement in general health.

4. There is evidence to show that removal of both semilunar cartilages in a complete synovectomy improves the function and gives greater relief from pain.

5. Synovectomy is contraindicated in acute gonorrheal arthritis, but has value in the chronic subacute stage of gonorrheal arthritis.

6. The improvement which is noted immediately after operation in cases of multiple proliferative arthritis is most striking. The explanation for this is doubtful. It has long been observed that these patients show marked lessening of symptoms in the joints after the administration of a general anesthetic or after protein shock. After synovectomy, all the involved joints are less painful and less swollen, and it has seemed to us that in the foregoing series a large percentage of this improvement has remained.

# A METHOD OF RECONSTRUCTING A VOLUNTARY SPHINCTER ANI \*

R. R. WREDEN, M.D.

Professor of Orthopedic Surgery in the Leningrad Medical Institute  
LENINGRAD, RUSSIA

Defective function of the sphincter ani is associated with great inconvenience for the patient and for those about him. It is not surprising, therefore, that numerous operative procedures have been suggested for the purpose of making a more or less firm closure of the lower end of the rectum when the sphincteric action is not perfect. The methods which have been most widely applied are: torsion of the lower end of the rectum according to the method of Gersuny or the replacing of the defective sphincter by a ring formed from the fascia lata according to the method of Thiersch.

An important and general defect, however, is common to all these closures; their activity is limited by the elasticity of the tissues of which they are formed. Active dilatation and contraction under the control of voluntary impulses are also impossible, thus there is not sufficient elastic contraction of the lower end of the rectum to retain gaseous and liquid feces. The generally accepted degree of contraction which allows easy introduction of the index finger into the rectum insures the retention of solid feces, but not of gaseous and liquid feces. A smaller opening either causes the patient to suffer from difficult defecation or destroys the closure owing to the pressure of the solid fecal masses during their passage.

All these considerations led me to attempt the restoration of a voluntary sphincter ani.

## REPORT OF A CASE

A man, aged 28, entered Engel's Hospital in September, 1926. He complained of incontinence of gas and feces. He was born with an atresia ani, and subsequent to the primary operation had repeatedly been subjected to various methods of surgical intervention for incontinence. The last operation consisted of the formation of a firm annular closure out of the fascia lata; the resistance of the latter, however, was soon overcome. Since then an intolerable condition of incontinence had again developed, so that the patient consented to any kind of surgical intervention.

The operation was performed under general anesthesia. The method of procedure was as follows:

1. The patient was placed in a position similar to that used during hemorrhoidectomy, his legs being fixed by means of a leg-holder.

---

\* Submitted for publication, Nov. 15, 1928.

\* Translated by I. R. Guerbatch.

2. Two vertical incisions were made on the right and on the left of the anal orifice, occupying the central part of the space between the anus and the tubera ischii; these incisions penetrated to the aponeurosis, covering the muscles of the perineum.

3. The fasciculi of the glutei maximi were then denuded by means of two crescent-shaped incisions with their convexity directed laterally and posteriorly. These were made behind the tubera ischii.

4. The fascia lata was then exposed through an incision 20 cm. long on the external surface of the femur. Two strips, each 18 cm. long and 2 cm. wide, were formed of the fascia lata.

5. Two forceps were then drawn transversely through each of the vertical incisions of the perineum anteriorly and posteriorly to the anal orifice. One pair

Fig. 1.—This and the following illustrations depict the operative procedure

of forceps was directed from right to left, the other from left to right, both passing through the subcutaneous tissue (fig. 1).

6. The ends of the fascial strip, caught by means of the two forceps on the right of the anal orifice, were drawn through the left vertical incision; the other fascial strip was drawn by means of the other two forceps in the opposite direction. As a result, the lower end of the rectum was encircled by two fascial loops.

7. Two forceps were then introduced through each of the crescent-shaped incisions into the vertical incisions on the same side, one of them being drawn above the fasciculi of the glutei maximi, the other under them (fig. 2).

8. The ends of the fascial loops were then caught by means of the forceps and drawn through the crescent-shaped incisions, where they were placed one on the other in a condition of slight tension and then fixed by means of a series of catgut sutures (fig. 3).

Figure 2

Figure 3

9. Cutaneous incisions were sutured with silk.

10. Defecation was delayed for ten days by the administration of opium.

Postoperative recovery took place without complications, and at present, ten months after the operation, the patient is able to retain not only feces, but gas. The index finger introduced into the rectum experiences a sensation of pressure when the *glutei maximi* are alternately contracted and relaxed as by the contraction of a normal sphincter ani.

I do not, of course, presume to draw unwarranted conclusions from this single case. My purpose is to acquaint my colleagues who have similar cases with a method which apparently gives one reason to hope for favorable results in the future.

# PLASTIC OPERATION FOR ANAL INCONTINENCE \*

HARVEY B. STONE, M.D.

BALTIMORE

Loss of control of the anal sphincter may result from distant lesions, chiefly involving the central nervous system and resulting in paralysis, or from local injuries to the muscle itself or to the nerves entering it. Of the second group of cases perhaps a majority are due to surgical operations, often undertaken with clear knowledge that incontinence may result, but nevertheless necessary. The condition is most distressing. It is frequently associated with a greater or less degree of prolapse of the rectal mucosa. Incontinence may be partial or complete. Often with a high degree of incontinence and marked prolapse the patient not only is unfitted for any form of social life, but is so uncomfortable physically as to be actually bedridden.

A number of methods have been described for the treatment of anal incontinence. I have tried most of them, from simple suture of the remnants of the damaged muscle to elaborate plastic operations with strips from the muscle margin of the gluteus maximus muscle. The experience has been uniformly disappointing. In 1925, the idea was conceived of making use of the preserved fascia of Koontz. This was utilized in two cases as a subcutaneous purse-string suture about the anal canal, introduced through two small incisions at the anterior and posterior commissures. The incisions were connected with each other by subcutaneous blunt dissection; the strip of fascia was threaded through the tunnels thus formed, and drawn up snugly and fastened. In both cases the fascia healed in, in spite of a thin serous drainage for several days. The results showed some improvement and both patients felt gratified, but much was left to be desired. As a matter of fact, improvement of actual control could not be claimed. What had been done was to tighten up a patulous outlet, give a feeling of greater perineal firmness and stop eversion of anal mucosa, but increased power of voluntary contraction was not found, nor could it have been expected.

In the summer of 1927, I received from a friend in Russia the manuscript of an article by Prof. R. R. Wreden,<sup>1</sup> of the Leningrad Medical Institute, entitled "A Method of Reconstructing a Voluntary Sphincter Ani." It employed a principle, as far as I know, entirely original, which at once made the impression of being a valuable addition to the methods of attack on anal incontinence. Furthermore, Pro-

1. Wreden, R. R.: A Method of Reconstructing a Voluntary Sphincter Ani, Arch. Surg., this issue, p. 841.

fessor Wreden reported having used the operation successfully in one case. The principle consists in slinging two loops of fascia subcutaneously from the gluteus maximus muscles; they pass around the side of the anus opposite the gluteus maximus from which they start and, since they interlock with each other, thus enclose the anal outlet in a ring of fascia. This ring can be tightened by the contractions of the glutei, drawing the loops of fascia tight. Professor Wreden utilized strips of the patient's own fascia lata for the formation of the loops.

Since reading Professor Wreden's article, I have had two patients with seriously damaged sphincter ani muscles, and have employed the principle briefly outlined with results that will be reported in detail

Fig. 1.—A and D indicate the incision to expose the margins of the glutei muscles. A bundle of muscle fibers from the edge of the gluteus is shown drawn up with a loop of tape in incision D. B and C indicate incisions to permit subcutaneous passage of fascia strips about the anal canal.

below. The actual operative steps are somewhat different from those described by Wreden, and instead of the patient's own fascia, strips of Koontz' prepared fascia were used. This was done to avoid the additional operation on the thigh. It is possible that in case 2 better healing might have resulted if autogenous fascia had been used. The steps of the operation are as follows:

#### METHODS

The patient is placed in the exaggerated lithotomy position and the usual preparation of the field carried out. Four separate incisions are made (fig. 1). Two of these are symmetrically placed on either side, along a line from the coccyx

to the tuberosity of the ischium. They are about 3 or 4 cm. long and are carried through the fat deep enough to expose the mesial margin of the gluteus maximus muscle. From this margin of the muscle a substantial bundle of fibers, as thick as one's index finger is bluntly separated in the long axis of the fibers, but not detached, so that it forms a band of muscle about which the fascia loops are later to be passed. The other two incisions are short, deep stab-wounds in the midline just in front of and behind the anus, 1 cm. from the mucocutaneous margin. Then by blunt dissection each lateral incision is connected subcutaneously with both the anterior and the posterior stab-wounds, and these two stab-wounds are connected with each other by blunt subcutaneous dissection around each side of the anal

Fig. 2.—Subcutaneous dissection completed for one side, with guide thread in place, running from *A* to *B*, to *C* and back to *A*. Loops of redundant thread are left projecting from incision *B* and *C* to facilitate pulling through of fascia, shown tied to end of guide thread.

canal. The dissection is simply done by pushing a closed curved clamp or similar instrument through the fat in the desired direction. Through the tunnels thus formed two strong linen threads are pulled, as shown in figure 2. Each thread starts from one of the lateral incisions, encircles the loosened strip of gluteus muscle, passes to the anterior midline incision, where a loop of it is pulled out, and then around the opposite side of the anal canal through the subcutaneous tunnel to the posterior midline incision. Here, again, a loop of the thread is pulled out. Then back again it goes subcutaneously to the lateral incision from which the start was made, but this time not passing around the band of gluteus maximus. To the end of the linen threads are firmly tied the strips of fascia to be used.

These should be at least 20 cm. long and about 1 cm. wide. The linen threads are then used as guides and tractors to pull the fascia strips through the same subcutaneous channels that they themselves have followed. The purpose in leaving a loop of slack in the linen threads at the midline incisions is to facilitate this pulling through process. The loop at the anterior incision is steadily and firmly pulled on until the fascia is drawn into the lateral incision, around the bundle of *gluteus maximus* and through the subcutaneous tract and appears at the anterior midline incision. It is drawn out of this incision until about 8 or 10 cm. of fascia protrudes through it. The loop of thread at the posterior incision is pulled on, making the attached end of fascial strip reenter the anterior incision and pass subcutaneously around the anal canal on the side opposite the lateral incision from which it started. It is then pulled out of the posterior incision until all slack in the fascia strip is drawn taut. Then the linen thread emerging from the original lateral incision is pulled on till the fascia is drawn out through the wound where it entered and its two ends are finally clipped together with a clamp. The opposite side is treated in the same manner. Figure 2 makes this procedure clearer than the verbal description.

At this stage of the operation, two loops of fascia are placed subcutaneously so that they encircle at one end the anal canal and at the other end a band of *gluteus* muscle, and interlock with each other about the anal canal. The two ends of each strip protrude from the same lateral incision. All that remains is to tighten the loops about the anal canal by tying the two corresponding ends of each strip to each other. The knot can be made in any way that the surgeon desires, and may if desired be further fixed by a transfixing suture. The degree of tension desired in tightening the loops must be left to individual judgment, but as there may be some tendency to relaxation later it would be wise to close the anal outlet quite snugly. The way in which tightening the fascia loops contracts a patulous anus is quite striking. After the loop ends have been fastened to each other securely, any excessive length of fascia strip is cut away; the knotted ends are dropped back deep in the lateral incisions and all incisions closed with a few interrupted sutures, without drainage. Figure 3 shows the complete operation.

#### REPORT OF CASES

CASE 1.—As a result of a surgical operation on the rectum which was followed by some postoperative bleeding and packing of the wound, a woman, aged 65, had almost completely lost the control of the muscles of the sphincter ani. This condition had persisted for several months and did not show a tendency toward improvement. On the contrary, the patient's condition was getting slowly worse. She would have involuntary bowel movements at frequent intervals whenever she was up and about, which made it necessary to wear a pad at all times and completely prevented either social or domestic activity. As a matter of fact, for a good while the patient had confined herself largely to her own room because of this condition. In addition to the incontinence described there was a partial prolapse of the rectal mucous membrane when the patient stood. This added considerably to her discomfort.

The operation already described was performed at the Union Memorial Hospital on Feb. 4, 1928, with the patient under ethylene gas. The details of the operation will not be repeated here. Following the operation, the patient made a slow but progressive recovery. It was some time before she regained her general strength, and it was at least three weeks before conclusive evidence of sphincter control could be recognized. The wounds all did well except the right lateral

incision, which discharged a thin serous drainage for perhaps five or six weeks and from which was discharged a small shred of fascia a few millimeters long and not any thicker than a piece of fine silk. Otherwise, the fascia healed in completely and months afterward could be plainly felt lying in its subcutaneous bed. The question of return of control was interesting. The bowels were purposely kept closed by medication for eight or nine days following the operation. When the first movement took place, the patient had scarcely more control than before the operation. She was greatly disappointed, and I was in doubt until it was recognized that the whole success of the operation depended on training the patient to use the glutei muscles voluntarily as a method of tightening the anal outlet. This was explained to the patient, who was intelligent and cooperative and eager

Fig. 3.—Both strips of fascia in place in subcutaneous tunnels, as shown by double dotted lines. The ends of the fascia strips are pulled taut, closing the anus, and are fastened with a knot about the bundle of gluteus fibers. Beginning closure of the small wounds.

to get well. The result of this new point of view was immediately apparent. By voluntarily tensing the glutei muscles, the patient was able to shut off the anal canal almost completely. With continued practice this habit became established, and ten weeks after the operation the patient was able to walk long distances and to ride in an automobile for an hour or more without discomfort from prolapse or loss of sphincter control. As a matter of fact, after the first few weeks, accidental escape of gas or feces became rare.

The patient was seen in May, 1928, about four months after the operation. At that time she herself felt that the success of the operation was almost complete,

and the result of examination was gratifying. All of the wounds were healed, with small, healthy, firm scars. The fascia was definitely in place and working. When the patient contracted the glutei muscles, the two loops of fascia snugly closed the anal canal. The patient had been able to resume her former activities almost entirely, going to the theater, taking drives and doing anything she wished within the limits of her general physical strength. She still tired easily and could not carry on beyond a certain length of time without exhaustion. She was not, however, hampered by either prolapse or incontinence. To me, this result seemed by far the best that I had ever seen as a result of attempts to cure loss of sphincter control.

*CASE 2.*—A white woman, aged 60, had a past history that is too extensive to narrate here in detail. It involved altogether twenty-seven different operations, most of which had been done about the rectum and the anus. The history dated back twenty years, at which time operation for supposed rectal tuberculosis had been done during the course of which the sphincter muscle had been removed. Following this a number of attempts had been made to improve the condition of the anal outlet, some of them having been done by the most distinguished surgeons in the United States. The results had been uniformly unsuccessful. At the time that I first saw the patient on March 5, 1928, her condition was just like that of the first patient described except that probably she suffered more extremely. The prolapse in this case was large, a mass eversion of rectal mucous membrane as large as a good sized peach taking place whenever the patient stood up, strained or made any movement that increased the abdominal pressure. This gave her a great deal of pain, and there was a constant mucous discharge. The circumference of the anus was a mass of broad and deep scar tissue, the result of various surgical procedures. No trace of a sphincter muscle could be recognized, and the patient did not have the slightest ability to contract on the examining finger.

The operation previously described was done in this case also, on April 10, 1928, at the Union Memorial Hospital under ethylene gas. Unfortunately, the outcome in this case was entirely different from that of the first patient. The postoperative convalescence was fairly satisfactory for the first two weeks. During this time the prolapse did not occur, and there was definite beginning control by the contraction of the glutei muscles. It became apparent that at about this time one of the strips of fascia was not going to heal in. Signs of infection appeared about the incision through which this strip of fascia had been introduced. The wound was opened and definite pus escaped; a short time afterward good sized masses of dead fascia strip were discharged from this wound. It was evident three weeks after the operation that the whole strip had been disintegrated, and most of it had been discharged. About this time the second strip showed the same process. The incision in the skin had to be opened, pus escaped and fragments of tissue also were discharged. The wounds continued to drain for a number of days longer and did not heal until all the fascia had disappeared from the wounds. As soon as the fascia strips commenced to disintegrate the prolapse began to return, and by the time that they had dissolved completely the patient's condition, as far as the rectal outlet was concerned, had reverted completely to what it was before operation. In other words, this operation was a total failure, owing to the infection of the wounds and the subsequent discharge from them of the fascia strips. The patient has been told that if she is willing to attempt another cure of her condition that the operation might be repeated, a strip of her own fascia being used, with perhaps somewhat better chances of success.

## COMMENT

The objection may be made against the use of prepared strips of dead fascia that they might provoke more chemical reaction in the tissues than would be the case with autogenous fascia strips. In a region like that about the rectum in which infection is an ever present possibility, the occurrence of a chemical reaction around the fascia strips might add to the chances of infection taking place.

# SUPPURATIVE PERICARDITIS

REPORT OF TWO CASES DRAINED BY THE POSTERIOR ROUTE \*

H. H. LOUCKS, M.D.

PEKING, CHINA

The subject of suppurative pericarditis has been thoroughly presented, the literature reviewed, and records brought up to date in the recent papers of Peterson,<sup>1</sup> Winslow and Shipley,<sup>2</sup> and Williamson.<sup>3</sup> Including the following reports, there are now 133 cases on record in which operation has been performed. Many unreported cases undoubtedly exist. In the discussion which followed the presentation of Peterson's paper before the Congress of Thoracic Surgeons in New York, the possibility of a posterior approach for drainage of the pericardium was mentioned. To demonstrate the plausibility of this method of approach in certain instances, the following cases are recorded.

## REPORT OF CASES

**CASE 1.—History.**—Sun Chan Chun, a Chinese soldier, aged 19, was admitted to the surgical service of the Peking Union Medical College on Dec. 17, 1925, four days after having been shot in the left axilla. The missile, a rifle bullet, was retained, and the roentgenologic examination at the base hospital at Nan Yuan, before admission, showed it to be lodged behind the left tenth rib in the posterior axillary line. There had been considerable hemoptysis following the injury, but for several days prior to admission there was only blood-tinged sputum. He had an increasing dyspnea.

**Examination.**—The patient was a small youth in marked respiratory distress. He was cyanotic. On admission, the temperature was 39.6 C. (103.3 F.); respirations, 36, and the pulse rate, 120. The blood pressure was 90 systolic and 70 diastolic. There was a small, clean and dry perforating wound in the left midaxillary line at the sixth interspace. The heart was pushed markedly to the right. Its impulse was felt 1 cm. from the midclavicular line in the fourth interspace, where there was also the right border of dullness. The left border of dullness could not be determined because of flatness at the base of the left lung. The cardiac sounds were clearly heard to the right of the sternum, but were distant on the left side. There were no murmurs. The rhythm was regular. The bases of both lungs were dull. On the left side, there was flatness up to the angle of the scapula. There were coarse ronchi throughout the chest, and fine moist râles at the base of the

right lung. The voice sounds were suppressed over the base of the left lung and amphoric above, and tactile fremitus was not elicited over the base. The percussion note was hyperresonant over the apex. The diagnosis on admission was: gunshot wound of the left side of the chest and lung, with hemothorax or pyohemothorax, and displacement of the heart to the right.

Examination by the medical service on the day following admission confirmed this diagnosis, and thoracentesis was advised to relieve the mediastinal pressure. Two unsuccessful attempts were made with an exploring needle to find fluid. Roentgen examination showed that the heart and trachea were pushed far to the right. On the left there was a large, dense, rounded shadow. The costophrenic

Fig. 1 (case 1).—Roentgenogram of the chest on admission to the hospital, Dec. 17, 1925.

angle was clouded. A rifle bullet lay just within and parallel to the tenth rib in the midaxillary line. The diagnosis of pericarditis with effusion, left hemothorax and retained foreign body was made (fig. 1). The same evening a pericardiocentesis was done by Dr. Kwan. The puncture was made in the fourth left interspace next to the sternum, and 100 cc. of a yellow turbid fluid was withdrawn. Smears showed gram-negative and gram-positive cocci in short chains. Cultures failed to show growth of the organisms.

The next day, December 19, the patient felt subjectively better and was less dyspneic, although his temperature remained high and his pulse rapid. Twenty-four hours later, his temperature had risen to 40 C. (104 F.) and his respirations were 39. On December 21, a pericardiocentesis was repeated in the same location,

and 320 cc. of reddish-yellow fluid was withdrawn. Smears showed streptococci, and by the next day cultures proved them to be of the hemolytic variety.

*Operation and Course.*—On December 22, a pericardiostomy was done. The boy was extremely ill and dyspneic, and had to be moved to the operating room in a sitting posture. With the patient under procaine hydrochloride anesthesia a curved incision was made, beginning in the midsternal line opposite the fourth rib and coursing outward and along the line of the sixth rib for several inches. This rib was exposed and its cartilage excised. The internal mammary vessels were ligated and divided, and the pleura carefully pushed laterally by a finger covered with gauze. The pericardial sac came readily into view and appeared red and edematous. It was grasped with Allis' forceps and incised parallel to and throughout the length of the intercostal opening. Four hundred cubic centimeters of pus, similar to that aspirated the day previous, was evacuated. Cultures failed to show growth of the organism. Fair exposure was obtained, but the incision was found to be 2 cm. above the lowest portion of the pericardium. It was felt, however, that the patient was too ill to justify further rib resection. Many plastic adhesions were already present near the base of the heart, and large flakes of fibrin lay free in the sac. These were removed. Drainage tubes were not inserted. The mouth of the wound was loosely packed with salt gauze and the patient returned to the ward more comfortable, subjectively, than he had been since his admission.

On December 25, two days after operation, flushing of the wound and pericardial sac with a solution of chlorinated soda was instituted every four hours. Drainage, however, was never profuse, and the small opening tended to close rapidly. The whole lower left side of the chest continued to be dull on percussion, the heart remained displaced to the right, and on December 26, roentgen examination showed that the posterior pericardium was still greatly distended. The shadow was 20 cm. in width, and extended to within 2 or 3 cm. of the left lateral wall of the chest (fig. 2). On December 29, the drainage from the wound became much more profuse and more purulent, and it was hoped that the posterior pocket was discharging.

At the same time the wound of entrance in the axilla reopened and began to show a slight discharge. The next day, December 30, the patient was taken to the operating room, still in a sitting posture, and this wound was explored. With the patient under local anesthesia, the course of the bullet was followed downward and posteriorly along the wall of the chest. The eighth rib had been fractured in the posterior axillary line, at which point the sinus entered the chest. A counter incision was made here, and a localized empyemic cavity containing about 100 cc. of pus was evacuated. The bullet lay at the bottom of this cavity and was removed. A partial resection of the eighth rib was thought advisable, but the patient's condition was such that the procedure was not considered justifiable at that time. Dakin tubes were inserted into the empyemic cavity and the sinus of the wall of the chest, and he was returned to the ward as quickly as possible. An x-ray film made the following day did not show any decrease in the size of the pericardial shadow (fig. 3).

On Jan. 2, 1926, the patient was brought back to the operating room and under local anesthesia 7.6 cm. of the fragmented eighth rib were removed. At this time a tense fluctuation could be felt through the compressed lung and thickened visceral pleura, but again it was thought that the patient's condition did not warrant further procedure. He was given a transfusion of 500 cc. of whole blood during the course of the rib resection. Throughout this entire period following admission the boy remained acutely ill, with marked dyspnea and high temperature and pulse rate. It was always a problem whether he could tolerate transportation to the

operating room or any surgical procedure—a condition which enforced the conservatism and multistaged operations employed.

On January 4, thirteen days after the anterior pericardiostomy, the posterior pericardium was approached through the already existing thoracostomy opening. Without anesthesia, an incision was made through 2 or 3 cm. of compressed, dark, already partially fibrosed lung. Eight hundred cubic centimeters of foul pus was evacuated. The patient's respiratory distress was immediately lessened, although his heart did not recede from its displaced position. Two large rubber tubes were inserted to keep the wound open. The patient was returned to the ward in good

Fig. 2 (case 1).—Roentgenogram of the chest on Dec. 26, 1925. Although 320 cc. of fluid was aspirated on December 21, and 400 cc. removed by pericardiostomy on December 22, the pericardium is still greatly distended.

condition. Cultures taken at the time of this operation failed to show growth of the organism.

After twenty-four hours, irrigations of chlorinated soda were instituted every four hours, as had been done with the empyemic cavity. There was profuse drainage. This was greatly facilitated by the posterior location of the incision, which afforded the optimum postural position with the patient semirecumbent in bed (figs. 4 and 5). According to the report on the roentgenograms taken on January 5, there was marked improvement in the pericardial and pleural cavities, and no fluid in either. A large, empty, thick-walled cavity persisted at the site of the previous left border of dullness (fig. 6).

For the next three weeks, the patient showed slow but steady improvement. On January 27, one of the two large drainage tubes was removed. At this time, the anterior wound was almost healed. On February 3, the second large rubber tube was removed, and several small soft rubber Dakin tubes were inserted. Irrigation was changed from chlorinated soda to saline solution because of the presence of a bronchial fistula, which would probably have been avoided by earlier removal of both large tubes.

Another transfusion of 500 cc. of whole blood was given a few days later, and an effort made to clean out a heavy hookworm infestation. On February 12, the records showed that the patient was steadily improving. He was brighter, stronger and had taken on some weight. The anterior incision had healed. There was little

Fig. 3 (case 1).—Roentgenogram of the chest on December 31, twenty-four hours after draining a localized empyema and removal of the foreign body. There is no decrease in the size of the pericardial sac.

discharge from the posterior sinus, which held only one Dakin tube. This last tube was removed on February 16.

On March 11, the report on roentgenograms showed that the appearance of the heart shadow and the left side of the chest was much improved. The diaphragm was now seen and its pleura was considerably thickened, but the pleura at the base was returning to normal consistency. The heart shadow was approximately normal in appearance, except for some persistent displacement to the right. There were increased lung markings on the left side, particularly adjacent to the hilum, but no evidence of a persisting pericarditis or empyemic cavity (fig. 7).

Fig 4 (case 1) —The wound of the anterior pericardiostomy, performed on Dec 22, 1925

Fig. 5 (case 1).—The wound of the posterior transpulmonic pericardiostomy, performed on Jan 4, 1926.

On May 23, the patient was discharged to the convalescent hostel. He had been on his feet about the hospital for some weeks previous to this time, without dyspnea or unusual acceleration of his pulse. The anterior pericardiostomy wound was completely healed. The posterior wound had contracted to a small sinus scarcely large enough to admit a probe. This connected with the bronchial fistula and, as proved by the discharge of several small pieces of bone, to an osteomyelitic rib.

During the summer months the lad was employed about the hospital grounds. He was kept at light labor out in the sun, and gained markedly in strength and weight. The sinus persisted. X-ray films taken on September 11, showed erosion

Fig. 6 (case 1).—Roentgenogram of the chest on Jan. 5, 1926, twenty-four hours after the posterior pericardial drainage.

of the eighth, ninth and tenth ribs and a definite but restricted area of clouding at the base of the left lung adjacent to the diaphragm. In general the lungs were clear (fig. 8).

The patient was readmitted to the hospital on September 28, and was operated on the next day. The sinus tract was explored under procaine hydrochloride anesthesia. Two paths were found; one leading to a sequestrum in the eighth rib, and the other to a small abscess still in communication with a bronchus. Resection of 7.5 cm. of the eighth and ninth ribs was done. The roof of the other sinus and of the abscess was removed. A little ether was necessary here, and, while coughing, the patient spat up some pus and thoroughly blew the remaining contents of the abscess through the wound. The edges of the skin were sutured to the pleura, and the wound and widely patent abscess cavity lightly packed with saline gauze.

By October 6, the bronchial fistula had closed, and remained closed permanently. The wound continued clean and granulated rapidly. By October 28, it had again contracted to a small sinus. The boy was discharged once more to the convalescent hostel.

The sinus persisted, and on November 29, the patient was again readmitted to the hospital. Two days later, under procaine hydrochloride anesthesia, this sinus was explored and found to lead to a sequestrum in the body of the tenth rib. Nine centimeters of this rib was excised together with a mass of adjacent scar tissue. Healing was prompt and complete. The patient was permanently dis-

Fig. 7 (case 1).—Roentgenogram of the chest taken on March 11, 1926.

charged from the hospital on Dec. 20, 1926, and from the dispensary on Jan 18, 1927.

He was brought back for reexamination on March 22, 1927. He was well and strong and able to do ordinary work without unusual fatigue or effect on his pulse. An electrocardiogram did not show any abnormality. The x-ray films showed that except for some generalized increase of the lung markings, a rather central position of the heart and the resected ribs on the left side, there was little to indicate the serious injury suffered by this patient something over a year previously (figs. 9 and 10).

CASE 2.—*History*.—Louis Ialungo, an Italian tailor, aged 30, was admitted to the surgical wards of the Cincinnati General Hospital on Oct. 8, 1922, from the

---

4. Permission to use this data has been kindly granted by Dr. George J. Heuer.

branch or tuberculosis hospital. His illness began about March 1, 1922, with cough, purulent expectoration, weakness, loss of weight and pain in the left side of the chest. His local physician made a diagnosis of tuberculosis and advised rest in the country. He went to a farm and lived in the open air for a month, returning home much improved. In May, an abscess developed on the right side of the back of his neck at the site of a shrapnel wound received in 1916. This was opened, and it healed. In June, an abscess appeared in the right inguinal region near the site of an old appendectomy scar. This continued to drain. In August, two months before admission, the patient began to have pain around his heart and over the left side of the chest. This was accompanied by progressive weakness and shortness of breath, so that he was soon confined to bed. He was admitted to the branch hospital on Sept. 30, 1922, with the diagnosis of pulmonary tuberculosis.

Fig. 8 (case 1).—Roentgenogram of the chest taken on Sept. 11, 1926. It shows a small empyemic abscess which communicated with a bronchus and erosion of the eighth, ninth and tenth ribs.

Examination revealed signs of an enlarged pericardium. This and a complicating pulmonary tuberculosis were confirmed by roentgenologic examination. The sputum was negative for tubercle bacilli, and there were 18,000 white blood cells. A pericardiocentesis was performed on October 6, and 20 cc. of pus was withdrawn from the pericardial sac. Examination of this did not reveal any tubercle bacilli; *Staphylococcus aureus* grew from the culture. The patient was transferred to the general hospital on Oct. 8, 1922, with the diagnosis of purulent pericarditis complicated by pulmonary tuberculosis, moderately advanced.

*Examination.*—On admission, the patient appeared sallow and anemic, and gave evidence of considerable loss of weight. He was not in pain when quiet, but the slightest effort caused him great distress. There was definite bulging of the entire

precordium from the second to the sixth interspace. The apex beat was easily seen in the fifth interpace, displaced laterally beyond the nipple line. It was diffuse and of wavelike character. The area of dullness was increased in all directions, but was not of the typical "pear shape." It extended 3 cm. beyond the left midclavicular line and 4 cm. beyond the right midclavicular line. The heart sounds were clearly heard over the entire precordium, but were rapid and embryonic. Murmurs or friction rub were not audible. The temperature was 102 F. Roentgen examination of the chest showed the trachea and bronchi to be deflected toward the right. The heart shadow was markedly increased in all diameters, especially on the left. The contour of the shadow was suggestive of pericardial effusion. An area of density

Fig. 9 (case 1).—Roentgenogram of the chest taken on March 22, 1927, three months after complete closure of all wounds.

at the base of the left lung merging with the heart shadow suggested the possibility of fluid there also. Considerable mottling of the fields of both lungs was present.

*Operation and Course.*—On October 10, the patient was operated on by Dr. George J. Heuer. With the patient under gas and oxygen anesthesia, an incision was made over the fifth costal cartilage; the cartilage resected and the pericardium exposed. It was at once apparent that there was no fluid between the pericardium and the heart, for the heart was in direct contact with the pericardium. Nevertheless, an incision was made through the pericardium, and it was found that the anterior surface of the heart was densely adherent everywhere to the anterior pericardial sac. An attempt was made to separate the pericardium from the heart, and a separation was made with great difficulty over an area perhaps

3 cm. in diameter. The procedure had to be discontinued, however, because the heart muscle was constantly damaged, causing bleeding. The operation in this region was therefore abandoned. The pericardium was closed with silk, as was the superficial wound throughout.

As Dr. Heuer felt sure from the physical and roentgen examinations that there was a large amount of fluid in the pericardial sac, the patient was turned over on his right side, and a rib was resected in the midaxillary and postaxillary line, with the idea of approaching the pericardium from behind. The lung was found adherent to the parietal pleura. An aspirating needle was inserted through the lung into the pericardial sac, and a syringe of thin pus withdrawn. With a blunt instrument the lung was perforated, and the posterior pericardium opened,

Fig. 10 (case 1).—Patient several months after complete recovery. Note the scars of the anterior and posterior incisions. The patient has returned to work.

with the immediate discharge of a large amount of purulent material. It could be positively determined that the pericardial sac had been entered, since, after evacuation of the fluid, a long instrument could be placed directly against the heart. The pericardial sac was drained with a fairly large rubber tube.

A subsequent x-ray picture showed diminution in size of the pericardial shadow, another proof that the pericardium had been drained.

Postoperative convalescence was satisfactory. The temperature and pulse rate promptly became lower. Drainage was good, and soon became of minimal amount. No irrigating solution was used until the second week, after which the cavity was washed out with salt solution daily. The tubes were removed after three weeks, and on November 10, one month after operation, the patient was up in a chair and in good condition.

Following this there was a flare-up of temperature, and the patient complained of night sweats and pain in his right side. The inguinal sinus was explored, and about 8 ounces of thick, creamy pus was evacuated from a pocket which lay along the lumbar vertebrae. Careful roentgen examination of the entire spinal column, both before and after injection of the inguinal sinus with bismuth paste, failed to show any evidence of a bony pathologic process or of origin of the sinus from the spinal column. A little later, the old cervical sinus reopened and continued to drain.

The patient was discharged on Dec. 21, 1922, ten weeks after operation. His pericardial wounds were healed, and both roentgenologic and clinical evidence showed that his heart had returned to almost normal size. Considerable infiltrate remained at the apex of the right lung and in the upper and middle portions of the left lung.

The subsequent history of this patient's disease is most interesting as it led up to the establishment of the final diagnosis on his last admission. The pericardial drainage wound remained closed throughout the rest of his illness, and there were no further symptoms referable to the heart.

On Jan. 2, 1923, two weeks after his first discharge, he was readmitted, complaining of pain in the lumbar region. The right inguinal sinus continued to drain through a long tract leading toward the tender area. A culture of the discharging pus yielded *Staphylococcus aureus*. Roentgen examination revealed the development of a lower dorsal and lumbar scoliosis with the concavity toward the right, but without destruction of bone. The pulmonary process was little altered. Following some clinical improvement after rest in bed, the patient was again discharged on Jan. 26, 1923.

On March 2, he was again readmitted because he had the same pain in the back. He had definitely lost ground since his discharge. The wound in his neck was closed, but the inguinal sinus was draining profusely. X-ray pictures taken with a rubber tube inserted into the sinus showed that it passed upward and posteriorly toward the spine. There was marked involvement with wedging and loss of substance in the bodies of the first and second lumbar vertebrae. The scoliosis had become more pronounced, and there was pain on pressure over the lower thoracic and lumbar vertebrae. The twelfth thoracic spine seemed definitely kyphotic. The abdomen was full and the flanks tender. A section of tissue taken for biopsy from the sinus tract showed only infected granulations. Several days after admission, there was a profuse pulmonary hemorrhage. A plaster jacket was later applied, and on March 28, the patient was returned to the branch hospital with the diagnosis of tuberculosis of the lungs and spine and a tuberculous psoas abscess, secondarily infected.

On April 8, the patient was admitted for the last time. He was returned because of the development of huge abscesses over both dorsolumbar regions. These were incised by Dr. Mont Reid. As the pus escaped over the skin, small yellow granules were observed, which on microscopic examination proved to be typical actinomycotic mycelia. Tissue curetted for section confirmed this diagnosis. The patient died on April 13, 1923.

#### COMMENT

The case for surgical drainage of suppurative pericarditis has been unquestionably established by the statistical work of Roberts,<sup>5</sup> Porter,<sup>6</sup>

5. Roberts, J. B.: Am. J. M. Sc. **114**:642, 1897.

6. Porter, C. B.: Ann. Surg. **32**:769, 1900.

Eliot,<sup>7</sup> Rhodes,<sup>8</sup> Klose and Strauss,<sup>9</sup> Williamson,<sup>3</sup> and Winslow and Shipley.<sup>2</sup> In the 133 cases in which operation has been performed, there have been seventy-five recoveries, or 56.4 per cent. In the twenty-nine cases collected by Klose and Strauss in which treatment by aspiration alone was given, there were but four recoveries, or 14 per cent. Cases in which treatment was not given have been universally fatal.

With regard to operative measures, Winslow and Shipley<sup>2</sup> have well pointed out that recovery is not so much a matter of route or technic of drainage, as of the time of operation and the accompanying conditions to which the pericarditis is secondary. Fourteen cases in which drainage was employed following infection from gunshot or stab wounds showed 100 per cent recovery. In those in which there was complicating osteomyelitis, pyemia or respiratory lesions, the recoveries varied from 33.3 to 49.3 per cent. Suppurative pericarditis is never primary, and the prompt recognition and proper treatment of the original lesion has as much to do with the prognosis as the prompt and proper drainage of the pericardium itself.

Concerning routes of drainage, practically every surgeon has attacked the pericardium through the anterior wall of the chest. This is the natural path of approach, since the pericardium lies in the anterior mediastinum adjacent to the sternum and costal cartilages, and this is the one area in which a transpleural operation can be avoided. However, as Curschman<sup>10</sup> first pointed out and as has since been confirmed by many writers, an extensive pericardial exudate lies almost wholly posterior to the heart itself. Postoperative walling-off or pocketing in the posterior pericardium, as in case 1, has been a common experience. The heart sometimes becomes so adherent to the anterior pericardium, as in case 2, that without doing definite damage to the organ itself, it is impossible to separate the two surfaces sufficiently to reach the exudate. Conner<sup>11</sup> has recently recalled the close approach of the pericardium to the posterior wall of the chest in cases of massive effusion, and recommends this route for pericardiocentesis in noninfectious (rheumatic) cases in which aspiration is considered necessary.

In the literature are mentioned several cases of transpleural drainage in which the pericardium was opened through an already existing thoracostomy wound for empyema (as in case 1) or in which the pleura was first opened with the mistaken diagnosis of empyema. Brinton and Collins<sup>12</sup> reported a case of the latter type, the pericardium

having been incised transpleurally in the fifth interspace in the anterior axillary line. The patient did not survive. Sibley,<sup>13</sup> and Steward and Garrod<sup>14</sup> reported cases in which an empyema was drained and a number of days or weeks later a bulging pericardium incised through this already existing wound, the general pleural cavity thus escaping infection. In Sibley's<sup>13</sup> case, the empyemic cavity lay anteriorly near the heart, and the opening was made just outside the nipple line. This patient did not survive. Steward and Garrod<sup>14</sup> evacuated an empyemic cavity by resecting a portion of the left eighth rib in the scapular line. Three weeks later, they opened a bulging pyopericardium through this same incision. Convalescence was uneventful. West,<sup>15</sup> in commenting on the presentation of this report, mentioned having seen another case of pericarditis in which similar drainage was instituted from behind and in which the patient also recovered. In the discussion which followed the presentation of Peterson's paper, Auchincloss mentioned a case in which posterior drainage was used by Whipple and in which the patient did not survive. I have not been able to find any other record of this case.

Posterior drainage of this sort has certain natural disadvantages which prohibit it from being the method of choice in any except those cases in which, because of an already existing pleuritis or empyema, there is reasonable evidence that the main pleural cavity has been sealed off from the operative field. It has the obvious advantage that in cases in which it can be safely employed it affords perfect postural drainage. Peterson<sup>1</sup> secures this in anterior exposure by placing his patients face downward upon the bed. This is an excellent procedure, but I am certain that many patients will not tolerate this position, particularly in the acute stage of their disease, when it is most important.

Any discussion of suppurative pericarditis always leads to the question of drainage and irrigation. Winslow and Shipley<sup>2</sup> have given complete statistical tables concerning the type of drainage materials used in all recorded cases, and the accompanying results. In both of the reported cases, short rubber tube drains were used in order to keep separated the edges of collapsed lung tissue and pericardium traversed by the incision. I agree with Peterson,<sup>1</sup> however, that wherever wide exposure and good postural drainage can be established, the use of any kind of tube or dam is unnecessary, if not actually harmful. Halsted clearly demonstrated the rôle of drains or any foreign body in abetting infection and the formation of adhesions in the peritoneal cavity. Beck

14. Steward, F. T., and Garrod, A. E.: *Proc. Roy. Soc., London* **1**:15, 1907-1908.

15. West, S.: *Lancet* **1**:560, 1910. Curschman (footnote 10).

and Moore<sup>16</sup> have shown similar or even greater sensitivity for the pericardial membranes. It seems unwise to insert any foreign body against an already damaged heart, and any attempt to drain the posterior pericardial recess through an anterior incision must of necessity do this. The beating organ can be relied on to keep its surrounding sac empty, provided a potential pocket of dilated posterior pericardium is not encouraged or maintained by a high anterior incision and a supine or semirecumbent position. Such pocketing occurred in case 1, and was the cause of the formation of the walled-off abscess which was later evacuated posteriorly. When the anterior approach is utilized, and it remains the method of choice for a large percentage of cases, I am of the opinion that resection of the fifth, sixth and seventh left cartilages with wide exposure down to the diaphragm and base of the pericardium, as advocated by Poole,<sup>17</sup> affords the best opportunity for complete drainage and consequently the best prognosis for recovery. This should be supplemented wherever possible by postural drainage as suggested by Peterson.<sup>1</sup>

Opinions differ greatly about the value and advisability of irrigations, particularly with solutions of chlorinated soda. The experiences cited by Miller and Andrus,<sup>18</sup> each of whom lost a patient apparently from uncontrollable oozing of blood caused by the constant friction of granulating pericardial surfaces, might prejudice one against this procedure. Hedblom, Poole and Auchincloss,<sup>19</sup> however, have all employed it with success and recommend the procedure. In the Peking Union Medical College, I have seen a surgical solution of chlorinated soda (Dakin's solution) used in three cases of suppurative pericarditis (including case 1), in all of which it gave most satisfactory results. Warm physiologic sodium chloride was used for the first forty-eight hours, after which, at two hour intervals, a surgical solution of chlorinated soda was instilled into the pericardium by a syringe and allowed to gravitate out. These measures seemed to have a most beneficial effect in helping to eliminate the infection.

#### SUMMARY

1. Two new cases of suppurative pericarditis are recorded: one secondary to a gunshot wound of the chest, the other secondary to what eventually proved to be actinomycosis.

2. Posterior drainage was instituted in both cases with recovery. In one case, a walled-off abscess of the posterior pericardium following an

18. Miller and Andrus, in discussion on Peterson (footnote 1).

19. Hedblom, Poole and Auchincloss, in discussion on Peterson (footnote 1).

anterior pericardiostomy was evacuated through a previously made posterior thoracostomy incision. In the second case, posterior approach was utilized after an unsuccessful attempt at anterior drainage had been made.

3. The advantage of the natural postural drainage of the posterior pericardium afforded by this method of approach is emphasized.

4. The limitations of this approach are suggested, as well as its practicability primarily in certain cases and alternatively in others in which anterior drainage is not feasible.

5. Postural, rather than tube or tissue, drainage is advocated.

6. The use of a solution of chlorinated soda by instillation is felt to be safe and of great value in most cases.

# STRANGULATED LEFT DUODENAL HERNIA

REPORT OF A CASE WITH RECOVERY \*

BRADLEY L. COLEY, M.D.

NEW YORK

Internal, or retroperitoneal, hernia is an unusual condition characterized by the protrusion of abdominal contents through a congenital, acquired or anomalous opening wholly within the abdomen. The vast majority of these internal hernias are also retroperitoneal, and they occur most frequently in the region of the duodenojejunal junction, about the cecum (pericecal retrocolic) and sigmoid colon. At these points rudimentary fossae are frequently found; when they attain sizable proportions, as they rarely do, they may contain abdominal viscera, and are then properly termed retroperitoneal hernias.

## INCIDENCE OF RETROPERITONEAL HERNIA

Some conception of the infrequent occurrence of retroperitoneal hernia may be gathered from the fact that Short,<sup>1</sup> in a survey of the literature in the decade between 1914 and 1924, was able to compile reports of only thirty-eight cases of retroperitoneal hernia of all kinds, including duodenal hernia, retrocolic or pericecal, hernia into the foramen of Winslow, intersigmoid hernia, hernia through the transverse mesocolon, hernia through the broad ligament and several anomalous retroperitoneal hernias. Of the thirty-eight cases, by far the largest number, fifteen in all, were of the left paraduodenal fossa. As the case here presented is of that variety, description will be confined chiefly to the left, or paraduodenal, form.

## CLASSIFICATION AND ETIOLOGY OF DUODENAL HERNIA .

An excellent monograph on the subject of internal hernia is that of Moynihan (Arris and Gale Lectures, 1897). He described nine fossae about the duodenum in which internal hernias may be found: (1) the superior duodenal fossa (Eppinger); (2) the inferior duodenal fossa (Treitz); (3) the left paraduodenal fossa (Landzert); (4) the right, or mesentericoparietal, fossa (Waldeyer), and (5) the mesocolic fossa. The unimportant, or rare, fossae are: (6) the posterior duodenal fossa (Gruber); (7) the duodenojejunal fossa (Huschke); (8) the recusus intermesocolicus transversus, and (9) the infraduodenal fossa.

The paraduodenal fossa first described in 1871 by Landzert is most frequently seen in the fetus or in the newly born. It is situated on the

1. Short: *Brit. J. Surg.* 3:48, 1915; 12:456, 1925.

left side at a little distance from the ascending duodenum and is formed by the fold of peritoneum (*plica venosa*) covering the inferior mesenteric vein; it is most apparent when the colon is pulled strongly upward.

A number of theories have been advanced to explain the formation of fossae and folds near the duodenum. Treitz attributed the herniation into these fossae to a combination of tense margins of the fossae, freedom of movement of the intestines and peristalsis. Waldeyer considered the elevation of the peritoneum by blood vessels to be an important factor. Toldt explained the fossae as physiologic adhesions. Other theories give the following causes: embryonic origin, as late descent of the cecum; formation of pockets during intestinal rotation; formation of fusion folds in fetal life and failure of the root of the mesentery to unite with the posterior abdominal wall. Moynihan, Langer and Toldt, Lower and Higgins and others expressed agreement with the view that the fossae into which herniation takes place are formed by fusion folds.

Edmund Andrews<sup>2</sup> considered the term "duodenal hernia" a misnomer and gave an embryonic explanation of its causation. He considered the condition "a congenital anomaly due to imprisonment of the small intestine beneath the mesentery and the developing colon." He expressed the belief that the prevalent conception that these large hernias originate in small peritoneal pouches and grow in size by gradual expansion of the sac is absurd and grotesque. He supported his belief with the following statements:

(1) Differential pressure is utterly lacking within the abdomen so that any *vis a tergo* to account for the formation or growth of such hernias is totally absent.

(2) There are hundreds of similar folds and fossae in the peritoneum, many of which are of much greater size, that are practically never the sites of such hernias.

(3) In all but a very small minority of cases reported, the degree of herniation has been total, or subtotal.

(4) A case of total hernia in a new-born infant has been reported (Left Duodenal Hernia of Vogt).

(5) The herniated viscera are never anything but small bowel. The presence of omentum has never been reported. In only one case (left duodenal hernia of Pybus) were a few inches of the descending colon herniated.

(6) In many of the cases there has been an almost universal growing together of the contents of the sac.

Andrews considered the adhesions to be derived from retroperitoneal tissue rather than due to inflammation.

Space does not permit of a full account of Andrew's theory on the production of duodenal hernia. His theory is plausible but not without objections. My case, for example, was by no means a total or

---

2. Andrews: Surg. Gynec. Obst. 37:740 (Dec.) 1923.

subtotal herniation, not more than 4 feet (122 cm.) of small intestine being found in the sac; nor were there any well organized adhesions between adjacent portions of contained intestine.

It does not appear to be necessary to assume differential pressure within the abdomen to account for progressive increase in the size of the hernia. Peristalsis can account for herniation of the small intestine into the lesser sac through the foramen of Winslow or through a rent in the transverse mesocolon as a result of gastro-enterostomy. Why, therefore, cannot the same mechanism obtain as an explanation for the progressive increase in duodenal hernias until they reach a large size? Brown gave other embryonic considerations which led him to discount Andrew's theory. The question, however, is far from settled at present.

#### AGE AND SEX

The average age, as found in thirty-five cases, was 34.7. The oldest patient was 68 and the youngest was 2. Five cases occurred in children under 15.

Of thirty-six cases in which the sex was stated, twenty-three occurred in males and fourteen in females. It is also interesting to note that in the seven cases collected by the author and in the case here presented the patients were males.

#### SYMPTOMS AND CLINICAL MANIFESTATIONS OF RETROPERITONEAL HERNIA

There are, no doubt, cases of retroperitoneal hernia in which the degree of herniation is so slight that symptoms are negligible. When the condition progresses to the point where symptoms are of clinical importance, it may assume one of several aspects: (1) recurrent attacks of subacute, or chronic, incomplete strangulation; (2) acute strangulation, and (3) presence of a palpable tumor. Some cases may include the features of all three types.

The case here reported gave a history of recurrent attacks of subacute strangulation, acute strangulation found at operation and the presence of a palpable mass.

It is a singular fact that correct diagnosis is rarely made prior to operation. Most cases are diagnosed simply as intestinal obstruction. As Moynihan pointed out, the characteristics of the abdominal tumor are fairly discernible, as they are noted on percussion and are limited to a definite area of the abdomen. On auscultation over the tumor, gurgling sounds may be audible. Definite peristalsis is likely to be present in cases of acute obstruction. These characteristics of abdominal tumor, however, may be taken for pancreatic, or ovarian, cysts.

Considering in retrospect the features of the case here reported, it would seem that a diagnosis of retroperitoneal hernia might have been

made prior to operation on the basis of (1) the history of recurring attacks strongly suggestive of incomplete intestinal obstruction, and (2) the presence of a large palpable mass to the left of the umbilical region in a patient on whom an abdominal operation had not previously been performed and who did not present the general appearance of one suffering from malignant disease.

#### TREATMENT

When symptoms of obstruction exist, either in the acute complete form or in cases presenting a history of frequent attacks of incomplete obstruction, the treatment should be surgical. A study of the records shows clearly that the results have been progressively more successful, especially during the last ten years. Short attributed this to the fact that operation is undertaken at an earlier stage. The mortality is undoubtedly influenced by the same factors that govern intestinal obstruction due to other causes but involving the same segment of the alimentary canal. Gangrenous intestine demands resection; despite this, several patients have recovered. The presence of important vessels in the neck of the sac (in the case of left paraduodenal hernia, the inferior mesenteric vein and in the case of right paraduodenal hernia, the superior mesenteric artery) should be constantly borne in mind. Division of the neck of the sac is therefore contraindicated.

In the case here reported, division of the peritoneum close to the vessels lying in the margin of the neck of the sac enabled the surgeon to stretch the constricting portion so as to permit reduction by a combination of taxis and traction. Whenever possible, the sac should be ablated or its mouth closed.

The postoperative care should follow the lines applicable to the management of intestinal obstruction due to other causes. Fluids by hypodermoclysis and intravenous administration of dextrose with due attention to the replacement of the chlorides, which are lacking in the blood (Haden and Orr), are points to be emphasized.

#### REPORT OF AUTHOR'S CASE

*History.*—A man, aged 52, was admitted to the Second Surgical Division of Bellevue Hospital, Dr. Harold E. Santee, director, on Oct. 26, 1926. The chief complaints were nausea, vomiting and abdominal pain. Two days prior to admission, the patient was seized with severe cramplike pains in the left midportion of the abdomen. The pain did not radiate; it had persisted since the onset and was accompanied by vomiting of greenish fluid. The vomitus did not contain blood and, up to the time of admission, was not fecal. On the day prior to admission, the patient took an enema, after which there was a tarry stool. Several normal bowel movements occurred thereafter.

The patient had yellow fever twenty years before admission. There was a history of recurring attacks of constipation occurring at intervals of five or six

months for the past twenty years. These attacks closely simulated the present attack and were usually associated with vomiting. The duration of the attacks was from two to three days. After these attacks, the digestion became normal. About six months before admission, during an exceedingly severe attack, the patient was admitted to a hospital in Bridgeport, Conn., where roentgen studies were advised, but he left the hospital before they could be undertaken.

The family history was irrelevant.

*Physical Examination.*—The patient was well nourished; he had severe pain and apparently was acutely ill. The temperature was 99; the pulse rate, 80 and respiration, 26. There was slight tenderness in the abdomen, which appeared to be more marked in the left midportion. There was slight rigidity of both recti, more pronounced in the left than in the right. Pressure over the middle sector of the left side of the abdomen revealed marked tenderness, and in this region there was a suggestion of a mass which could not be clearly outlined, owing to the degree of tenderness present. The percussion note elicited was tympanitic, with partial obliteration of liver dullness, more marked on the left.

There was no rectal tenderness; masses were not felt.

The results of the remainder of the physical examination were normal in all essential particulars. The white blood cells numbered 11,000, 90 per cent of which were polymorphonuclears.

Examination of the urine showed: albumin, 1 plus; a few granular casts; no pus or red blood cells.

Various diagnoses were suggested prior to operation, among them being perforated gastric ulcer, diverticulitis of the sigmoid with abscess, acute pancreatitis and strangulated internal hernia.

*Operative Procedure.*—On Oct. 26, 1926, when the abdomen was opened through a left para-umbilical incision, an ovoid mass approximately 7 inches (17.7 cm.) in diameter presented itself immediately beneath the parietal peritoneum but not attached to it. There were a number of large vessels in this peritoneal layer. Inspection and palpation revealed the presence in the mass of loops of intestine together with some fluid. An opening was made in this sac and disclosed about 4 feet (122 cm.) of small intestine, which was markedly hypertrophied, the walls being fully  $\frac{1}{4}$  inch (0.6 cm.) thick. At one point a definite beginning intussusception was present, but the continuity of the lumen was not markedly encroached on. A considerable amount of straw-colored transudate, tinged with blood, escaped from the sac when it was opened. There were strands of yellow fibrinous exudate on the intestine, which was a deep cherry red, showing a definite vascular encroachment of this loop. The lesser peritoneal sac was exposed through an opening in the gastrohepatic omentum and was found empty. Coils of collapsed small intestine were felt free in the lower part of the abdomen, and the cecum and the ascending and descending colon were identified and occupied their normal positions. The transverse colon and the stomach were pushed upward beneath the costal margin by the presence of this mass. The neck of the sac faced to the right, and its edge contained a large vessel which was readily palpable. The sac lay for the most part to the left of the midline. A distended, afferent and collapsed loop of small intestine was seen to enter and leave the cavity.

A left rectus muscle-splitting incision was made in the midpoint opposite the umbilicus. The mass was exposed and the sac opened. The contents were released and freed without division of the vascular neck of the sac by stretching and dividing fibrous bands close to this vascular area. The intestine was pushed from the left side and pulled from the right beneath this vascular band until it had been completely reduced. The sac was then inverted by passing it beneath this band and

the greater portion of it excised, its edges being closed together with a running locked suture of no. 1 plain catgut. The intestine, which was involved in the sac, was again inspected; as it appeared viable, it was replaced in the abdomen. Closure by layers was effected with no. 1 chromic catgut for the peritoneum and silkworm gut retention sutures for the rectus sheath. Drainage was not instituted.

*Postoperative Course.*—Following the operation, fluids by mouth were withheld for thirty-six hours, during which time the patient received two hypodermoclyses of 1,500 cc. each on the first postoperative day and three of 1,000 cc. each on the second. Vomiting occurred on the second day as a troublesome symptom.

Author's case of strangulated left duodenal hernia; note proximal coils of distended small intestine, and collapsed distal coils.

Gastric lavage proved effectual in promptly clearing it up. By the third post-operative day the patient was beginning to take fluids without vomiting, and colonic irrigations were giving satisfactory results. On the fourth day an enema was productive of a large, dark brown, fluid stool accompanied by much flatus. The highest temperature was reached on the night of the fourth postoperative day; at this time, the patient had a productive cough, and the question of pulmonary involvement was raised.

Thereafter, recovery continued without any untoward incident, except that there was a heavy feeling in the abdomen. The wound healed by primary union, and the patient was discharged on Nov. 27, 1926, his thirty-second postoperative day.

*Follow-Up Notes.*—The patient returned to the follow-up clinic for examination, March 20, 1927, approximately five months after his operation. At that time he was back at work, was still having considerable trouble with gas, and a small postoperative ventral hernia was present. He was given an abdominal belt and requested to return for subsequent observations, but he never returned to the clinic. All further efforts to trace him failed.

The first series of collected cases is that of Moynihan,<sup>3</sup> who found reports of eight patients successfully operated on and ten in which death occurred with or without operation. In 1914, Short<sup>4</sup> presented fifteen additional case reports, in eleven of which the patients recovered after operation and in four of which they died. In a second study, published in 1925, he<sup>5</sup> gathered fifteen more cases that had been reported in the decade from 1914 to 1924; eleven of the patients recovered and four died. Short did not include cases discovered post mortem in which the condition was unsuspected during life, but confined himself to those in which symptoms were present and, in most cases, operation performed.

In a review of the literature from January, 1925, to July, 1928, reports have been obtained of seven cases of left paraduodenal hernia in which operation had been performed. I report the eighth. In addition, Liebers<sup>6</sup> recorded observations made at autopsy in a case complicated by miliary tuberculosis in a girl of 3, and Forlini<sup>7</sup> contributed reports of five cases, all of which were discovered at autopsy. Most of these patients died from other causes, and operation was not indicated or performed in any of them. During this period there have been reports of four cases of right duodenal hernia in which operation was performed.

Since the six cases of left paraduodenal hernia previously mentioned were discovered only at autopsy, I shall not consider them further.

A summary of the eight authentic cases is given in the accompanying table.

#### DETAILED DESCRIPTION OF CASES REPORTED SINCE 1924

CASE 1.<sup>7</sup>—A man, aged 22, was well until Jan. 27, 1927. He then developed severe and colicky pain in the left upper quadrant of the abdomen. He was admitted to the hospital on Jan. 28, 1927, with a temperature of 97, pulse rate 80 and respiration 20. He was quite prostrated, perspired freely and suffered at intervals of from ten to fifteen minutes with acute abdominal pain, mostly referred to the left upper quadrant.

Examination showed slight distention above the umbilicus. During a spasm of pain, the abdomen was rigid. Some dulness was present on the left flank.

6. Liebers: *Ztschr. f. Kinderh.* **42**:676, 1926.

7. Forlini: *Arch. ital. di chir.* **16**:482, 1926.

There was no tenderness over McBurney's point, but marked tenderness was present over the left upper quadrant just to the left of the midline about 1 or 2 inches (2.5 or 5 cm.) above the umbilicus. The leukocyte count was 17,500; the urine was normal. The case was considered one of intestinal obstruction.

Operation was performed on Jan. 29, 1927, under intratracheal ether. A left rectus incision was made, extending to just below the umbilicus. When the abdomen was opened, bloody fluid was found. The left upper quadrant was then explored and several loops of contracted small bowel were drawn up, commencing about 18 inches (45.7 cm.) below the duodenojejunal flexure. Above the contracted bowel, a mass of small bowel was found herniated into the cavity bounded above by the transverse mesocolon, and the hernia was held in its position by a band of omentum extending from the left transverse mesocolon obliquely down

and anchored into the tip of the appendix. The omentum, which had caused the hernia, was removed. When the herniated mass was removed, the color and contour of the bowel became normal. There was no necessity of resection. The abdomen was closed without drainage. Recovery was uneventful.

After careful consideration of this case report, it would seem that it was unquestionably an example of a left paraduodenal hernia.

CASE 2.<sup>s</sup>—A man, aged 33, six hours before admission had severe abdominal cramps and vomiting, but no gas or bowel movement. The abdomen was distended and painful; the tongue was dry; the pulse was fast and weak. The patient had had abdominal pains for two months prior to admission; flatulence and constipation had occurred frequently but had disappeared when cathartics were used.

Immediate operation was performed under general anesthesia. Incision was made in the midline. In the left half of the abdomen, a round elastic tumor covered with a shining serous membrane was found. To the left of the tumor the empty descending colon was stretched down on the right, the cecum drawing toward the midline. In the upper part of the body cavity were seen a few loops of inflated small intestine. On drawing the cecum to the right, one found a narrow hernial opening in which two pieces of intestine were confined. The projecting end of the ileum was caught at its entrance into the cecum so that a portion of the wall of the latter was also included in the ring. The strangulating ring was separated with the index finger as was the anterior wall of the sac almost up to the descending colon. In the sac, which proved to be a retroperitoneal pouch, there was a completely gangrenous section of small intestine. Resection was effected by end-to-end anastomosis. The abdomen was closed. Part of the ileum, 327 cm., was resected. No postoperative complications occurred. The patient left the hospital in one and one-half months.

After working two and one-half months, he was readmitted with subacute intestinal obstruction. On palpation, pain was felt in the left part of the abdomen under the ribs toward the umbilicus. Incision was made in the old scar, and many adhesions were found. When the intestines were pushed to the right and the flexura lienalis to the left, a large cavity was revealed; it was limited on the left and above by the large intestine and led into the abdominal cavity proper. The small intestine issued from the depths of the hole under the transverse colon. This large cavity, covered with serous membrane, was a remnant of the retroperitoneal pouch, the anterior wall of which was divided at the first operation and which had remained as firm scar tissue adhesions between the parts of the flexura lienalis. This coalescence brought the two parts of the large intestine nearer together and formed a pointed corner between them. After all the adhesions were separated, the wound was closed; it healed by first intention. The patient remained under observation for one month. It was necessary to use cathartics. He complained steadily of abdominal distention and painful peristalsis. When he left the hospital he had gained in weight.

CASE 3.<sup>o</sup>—A boy, aged 9 years, had had an attack which began thirty days before admission to the hospital, with a rise in temperature, abdominal pain, vomiting and hiccup. The vomitus was not fecaloid. For ten days, the patient had suffered from colicky abdominal pain and fever, nausea and vomiting of almost all food taken. The boy was thin and anemic; the pulse was weak and rapid. The abdomen was symmetrical; the left half in the region above the umbilicus was pushed out, and the rest was notably flat. In the distended region, there were thick loops marked by painful peristaltic movements.

In the left half of the abdomen, palpation revealed a resistant mass, the size of a large orange, of soft, elastic consistency, like a vesicle full of air. The outlines of the mass were not clear.

Median laparotomy under ether revealed an internal hernia near the duodeno-jejunal angle. Moderate inflammation of the peritoneum and proximal loops distended with fluid and gas were found, the latter completely empty and contracted. The first loop was covered for the most part by a peritoneal fold which constituted the anterior wall of a pocket the entrance of which was near the duodeno-jejunal angle. It was comparatively easy to retract the entire loop from the sac. There were no evidences of stricture on the loop, only a slight modification of the coloring and the consistency of the intestinal wall.

The loop was replaced in the abdominal cavity, and the edges of the neck of the sac were sutured with the wall. The postoperative course was regular. Emission of gas and feces occurred after twenty-four hours. Food was taken in abundance and was well tolerated on the second day. The condition was cured, and the patient quickly improved in general health.

CASE 4.<sup>10</sup>—A farmer, aged 31, complained for eight months of repeated abdominal cramps associated with a rise in temperature, tympanites, vomiting, obstipation and loss of weight. For three weeks prior to operation, a fluctuating tumor, the size of a man's fist, was palpable in the left side of the abdomen. At physical examination the abdomen below the left costal arch and at the level of the umbilicus showed an uneven and soft, slightly resistant mass, not adherent to the abdominal wall. The intestinal outlines were not palpable. Haber's syndrome was absent. Abdominal pain or distention was not present.

At operation the omentum was found adherent to the anterior abdominal wall, the tumor and the adherent loops of small intestine. The slightly oval tumor, the size of a man's fist, was found adhering above to the mesocolon and below to the spinal column, and was enveloped in a soft, elastic, grayish-white, fibrous membrane. There was no fluctuation. The tumor was isolated and found to be a duodenojejunal hernia, consisting of 50 cm. of small intestines of which the first jejunal loop had entered the hernial sac at the flexura duodenojejunalis. After the sac was opened, the distended small intestine was emptied and withdrawn into the abdominal cavity. The sac was reduced, and the abdominal wall sutured. The wound healed by primary intention. The patient made an excellent operative recovery. Two and a half years later, he had gained 14 Kg. in weight, had regular bowel movements and no pain.

CASE 5.<sup>11</sup>—A man, aged 48, entered the clinic, June 30, 1924. He had suffered from pains at the level of the umbilical region for many years in the form of intermittent crises, accompanied by vomiting, tympanism, cold sweats and constipation. The pains "bent him double" for two or three days, and thereafter digestion was difficult. Evacuation had never been easy. The patient entered the hospital after an especially acute attack.

He was thin and undernourished. Hyperesthesia of the umbilical region was present, with a vague sensation of a swelling, painful on pressure. The upper part of the abdomen was slightly distended and tympanitic. Concentrated enemas caused the expulsion of only a small amount of fecal matter.

Roentgenographic examination showed obstruction in the small intestine, below the greater curve of the stomach and at the level of the duodenum. The diagnosis was internal hernia, probably in one of the duodenal fossae.

Median incision was made under ether, operation being performed as quickly as possible. The duodenum was reached by raising the transverse colon. A part of the small intestine was a little distended and penetrated into the peritoneal sac at the left with its opening toward the right. Guided by touch, the operator slowly drew out the jejunum. The cavity admitted three fingers. At one point in the herniated area a stricture was formed by the viscera, but without greatly diminishing its caliber. The sac was not obliterated because the surgeon feared doing too much, and the probability of the intestine again occupying this fossa did not equal the risk of prolonging the anesthesia. Twelve hours after the operation, a dose of solution of pituitary was injected.

---

10. Erdely: *Deutsche Ztschr. f. Chir.* **205**:120, 1927.

11. Hernandez: *Rev. de med. y ciruj. de la Habana* **31**:92, 1926.

Convalescence was somewhat difficult, but after the eighth day the patient recovered rapidly. The abdominal wall supplicated. In twenty-nine days, the patient was cured. The author expressed the belief that this is the second or third case in the literature in which a diagnosis was made before operation and the patient recovered completely after operation. The length of time the patient was observed after operation was not stated.

CASE 6.<sup>12</sup>—A man, aged 37, entered the surgical clinic of the Hôtel-Dieu in Paris, in February, 1922, for a tumor which had developed at the left of the median line of the abdomen. In 1917 he suffered with indigestion as a result of poor nutrition and on absorption of fatty foods. In July, 1920, he had intestinal trouble and alternating attacks of diarrhea and constipation, the diarrhea being preceded by a slight sickness (colic and sometimes vomiting). All these symptoms ceased, however, when diarrhea succeeded constipation. Six weeks before he came to the clinic he was awakened one night by dull and continued pains. The presence of a tumor, which had existed since that time, was ascertained.

At admission on February 13, a tumor the size of a mandarin, a little dented, stationary and sensitive to pressure, was found between the umbilicus and the left costal edge. A barium sulphate enema revealed that the colon was filled regularly without the least stoppage at any point. The splenic angle was situated high under the diaphragm. It was ascertained definitely by palpation that the tumor was slightly posterior to and independent of the colon.

Operation was performed on March 13, 1922, by Hartmann. A left rectus incision was made, and it was possible to lift up the colon and see a red, lobed tumor, which was stuck to the mesenteric edge of the first jejunal loop and adherent to the fourth portion of the duodenum. As the growth was considered a ganglionic retroperitoneal tumor, the abdomen was closed, and the patient was cured temporarily. A month later pains reappeared more frequently, were more distressing and were accompanied by a hardening of the tumor.

In August, 1922, digestion became slow and difficult, and the patient grew thin. Pains were felt throughout the left side of the hypochondrium, and were especially severe after meals.

A roentgenologic examination was made by means of a barium sulphate meal, so that the intestinal tract could be studied.

The general condition was precarious. The thorax was very long; the ribs were prominent. The panniculus adiposus was totally absent. The patient weighed only 40 Kg. Duodenal stagnation was clear and the author proposed duodeno-jejunosomy. The patient refused, however, and treatment followed. The urine did not contain sugar or albumin; the Bordet-Wassermann test was negative. In October, the patient weighed only 36 Kg., and the pain grew more intense. Finally, operation was performed.

A median incision was made; the liver was found to be normal, the stomach relatively small and the pylorus thin and open. Numerous adhesions between the gallbladder and the duodenum, due to the previous operation, were liberated. The abdomen was full of large ganglions, and the tumor, which was retroperitoneal, was large and resistant.

Jejunostomy was performed according to the technic described by Gregoire.<sup>13</sup> The angle formed by the mesenteric and colonic vessels was sufficiently opened so that an anastomosis could be made with a straight intestinal needle in two planes with fine silk.

12. Christophe: Bull. et mém. Soc. nat. de chir. 52:1000, 1926.

13. Gregoire: J. de chir. 19:499 (May) 1922.

A puncture was then made into the tumor about a fingerlength below Treitz' ligament, but gave no result. At this place, the posterior parietal peritoneum, then a rather thin wall which gave access to a pouch containing from 50 to 60 cc. of bloody fluid, was incised. A sponge brought out some whitish detritus like milk curds. A fragment of the wall was taken for examination. A drain was placed in the sac and another in the left side, and the abdomen was closed.

The drain in the side was removed on the tenth day; during the first few days, from 200 to 250 Gm. of whitish liquid, i.e., ingested milk, was removed through the other drain.

Microscopic examination of the ganglions showed only lesions of chronic inflammation, and to the author's great astonishment the wall of the cyst had the structure of normal intestine.

The quantity of liquid drained diminished progressively; digestion became good and the appetite excellent. It was hoped that the intestinal fistula would heal, but on November 21 fever set in; laryngitis developed, and the patient died on November 23.

CASE 7.<sup>14</sup>—A man, aged 22, complained of vomiting, abdominal pain, nausea, belching of gas and failure to pass flatus or fecal matter for six days. For seven years he had suffered from similar attacks occurring about once a year and lasting for from two days to a week. Considerable tenderness was present in the right lower quadrant, but pain, increasing in severity, seemed to be most severe in the left lower quadrant. The patient had not passed bloody stools. The history was otherwise essentially unimportant.

On physical examination, the patient was in great pain, with rapid pulse of poor quality and with subnormal temperature. The abdomen was distended. Generalized tenderness and rigidity were present. There was dulness in both flanks. Tenderness over McBurney's point was more marked than elsewhere. The preoperative diagnosis was acute appendicitis.

The abdomen was opened through McBurney's incision, and considerable free fluid was found in the peritoneal cavity. While an attempt was being made to remove the appendix, a pronounced retroperitoneal tumefaction was discovered, and in order to determine its character, a gridiron incision was enlarged by cutting half way through the rectus sheath and muscle to enable the introduction of the entire hand into the peritoneal cavity. A considerable portion of small bowel was found to have herniated retroperitoneally through an opening to the left of the vertebral column, particularly in the region of the paraduodenal fossa, the hernial opening being about the size of a fist. The exact relation of the hernial ring could not be made out on account of the poor condition of the patient. The bowel was pulled out of the hernial sac and brought into the main peritoneal cavity. The part of the bowel that had herniated was distended and blue.

The patient passed bloody stools the first day after operation and vomited repeatedly. Gastric lavage was given frequently. Saline hypodermoclyses were administered. On the third day, the vomiting was fecal, and abdominal distention increased. The temperature was 101 F. and the pulse rate 120.

With the patient under 1 per cent procaine hydrochloride, the peritoneal cavity was opened through an incision in the left flank. A moderate amount of clear fluid was found free in the peritoneal cavity. Volvulus and a proximal loop of the jejunum were present. The hernial opening was examined and found empty. Jejunostomy (evidently high up) was performed by the introduction of a large silver catheter securely placed by pursestring suturing of the presenting

---

14. Eitel, G. G.: *Journal-Lancet* 46:131, 1926.

intestine stitched to the parietal peritoneum. During the operation, the patient was given 1,000 cc. of physiologic sodium chloride solution. There was considerable improvement on the following day; the temperature was 101 F. and the pulse rate, 120. One thousand cubic centimeters of 3 per cent saline solution was given. The general condition grew better, and the catheter was removed on the fourth day. During the three following days, rapidly progressive emaciation and evidence of marked dehydration were noted; no doubt these changes were due to excessive loss of fluid because the fistula was so high up in the intestine. Following a transfusion of blood on the thirteenth day after the first operation, the fistula was closed by resection of about 6 inches (15 cm.) of small intestine; a full excision of the mesentery and an end-to-end anastomosis were made, catgut and fine silk being used for sutures. For two days following, the patient had a stormy course, with rapid pulse, fecal vomiting and marked abdominal distention. He was given repeated gastric lavage, hypodermoclyses with 3 per cent saline solution, a digitalis preparation and small doses of morphine. On the third day he began to improve. At present, he is well and back at his regular work.

#### COMMENT

In the cases characterized by chronic intestinal obstruction, a laparotomy with reduction of the hernia should be successful in the majority of uncomplicated cases. In cases characterized by symptoms of acute intestinal obstruction, however, the prognosis is dependent on several factors, the most important of which is undoubtedly the rapidity with which operation follows the onset of symptoms. Delay until toxemia and paresis have occurred makes the outlook much more hazardous. Several patients in the series reported in the literature withstood multiple operations, including intestinal resection.

One of the most noteworthy of these is the patient of Eitel, who survived three operations, the last of which was the resection of 6 inches of jejunum. From a study of his case report, it would appear that hypertonic saline solution and blood transfusion were factors in the fortunate outcome.

Kuschewa and Malinowsky's patient also survived resection and intestinal anastomosis.

The combined statistics show that there were thirty-four recoveries and seventeen deaths.

#### CONCLUSIONS

1. Retroperitoneal hernia is a relatively rare condition, since only thirty-eight reported cases of all types were found by Short in a ten-year period.

2. Hernia into the left paraduodenal fossa is by far the most common variety of retroperitoneal hernia. Forty-three cases of left paraduodenal hernia which produced symptoms during life were reported by Short in 1925. I have added seven more cases and report an eighth, bringing the total number to fifty-one.

3. The symptoms are for the most part those of intestinal obstruction, but the presence of a mass to the left of the median line is important. Diagnosis is seldom made before operation.

4. Treatment consists in reduction of the herniated intestine with care to avoid injuring the vessel which lies in the free edge of the neck of the sac. Partial excision of the sac or obliteration of its cavity is advisable whenever possible. The condition of the bowel may necessitate resection.

5. The mortality rate after operation has been decreasing, there being one death in a recent series of eight cases. This may be attributed in part to more prompt surgical intervention in cases presenting symptoms of intestinal obstruction. The mortality rate will probably approximate that which obtains for cases of intestinal obstruction in general. The intravenous use of dextrose and hypodermoclyses of saline solution are of value in the postoperative care.

# INTUSSUSCEPTION DUE TO INTESTINAL LIPOMA IN AN ADULT, FOLLOWED BY GANGRENE IN THE ABDOMINAL WALL

PLASTIC OPERATION FOR REPAIR OF ABDOMINAL WALL \*

J. SHELTON HORSLEY, M.D.

RICHMOND, VA.

J. W. M., a farmer, white, aged 67, was admitted to the hospital on Dec. 14, 1927, complaining of great pain in the abdomen, constipation and vomiting. Two days before admission, after eating a big dinner, he was suddenly seized with cramplike pains in the lower part of the abdomen. The pain was severe, and the lower part of the abdomen became somewhat distended. He took enemas and purgatives. There were fair results from the enemas, but the purgatives accentuated the pain and did not produce results. He then began to vomit and soon vomited large quantities of brown, fecal smelling material. A diagnosis of intestinal obstruction was made. The patient had had a somewhat similar but much milder attack about ten years before admission, but soon recovered. He had been fairly healthy most of his life, but for many years had had chronic constipation which had been much worse recently. He had malaria and typhoid fever when a young man.

On admission, the patient's temperature was 99 F., the pulse rate 96 and respirations 18. He was vomiting, and gastric lavage brought away 16 ounces (473.1 cc.) of foul brown fluid resembling liquid fecal matter. Marked abdominal distention and pain were present. The patient was quite fat. Under a combination of local, ethylene and ether anesthesia, a *McBurney incision* was made. When the peritoneum was opened, a considerable quantity of straw-colored fluid was evacuated. The intestines were greatly dilated. An indefinite soft mass was felt in the upper right side of the abdomen. The cecum could not be demonstrated. This mass could not be brought into the wound, so the incision was enlarged. The greatly distended bowels were delivered into the wound. It was impossible satisfactorily to manipulate them because of the distention, so an intestinal loop was opened; first a purse-string suture was placed and then the bowel was incised within the grasp of the purse-string suture, and a large, soft rubber tube was inserted. Through this tube much fecal matter and gas were evacuated, and the distention was reduced. A small amount of fecal matter was spilled while this opening was being made, but it was mopped up and the wound was flushed with an antiseptic solution. After the tube was removed, the purse-string suture was tied and reinforced by two similar sutures of linen. The incision was again extended, this time by incising the right rectus muscle upward from the inner end of the enlarged *McBurney's incision*. Then the upper mass could be delivered into the wound. It proved to be the cecum, into which about 3 feet (91 cm.) of the lower ileum had become invaginated. The intussusception was reduced. The bowel was not gangrenous, but a considerable

Fig. 1.—Lipoma of the ileum, measuring 2.5 by 2.5 cm. Most of the surface is covered with intestinal mucosa.

Fig. 2.—Section of lipoma from the ileum, showing distinct capsule enclosing the fatty tissue.

Fig. 3.—Diagrammatic drawing of lipoma of intestine. It should be noted that most of the lipoma projects into the lumen of the bowel.

quantity of serous fluid had accumulated in the peritoneal pocket formed by the outer coats of the bowel involved in the intussusception. After the ileum was reduced entirely, the ileocecal fold of fat was sutured to the mesentery with plain and tanned catgut in order to make the tissues stiffer and prevent a recurrence of the intussusception.

About 18 inches (45.7 cm.) above the terminal ileum was a tumor which appeared to obstruct the lumen of the bowel. It was soft and seemed to be a fatty growth. While it projected slightly from the concave side of the bowel, most of it was in the lumen. It apparently was the head of the intussusception and doubtless caused the intussusception by partially obstructing the fecal current and by being forced down by peristaltic waves. After the bowel was clamped with soft-bladed clamps, the growth was removed through a transverse incision. The wound was closed by suturing the wall of the bowel with a continuous suture of no. 00 tanned catgut and then burying this with two rows of linen placed as continuous

Fig. 5.—Rubber patch from an inner tube and three pieces of metal that were used for temporary repair of the abdominal wall. The rule is in inches.

right-angle sutures. An oblique enterostomy was made just on the oral side of this wound, and in it was placed a soft rubber catheter. An interrupted suture of 00 tanned catgut was placed in the bowel where the catheter emerged and was passed through the parietal peritoneum so as to fix the site of the enterostomy to the abdominal wall. The straight incision upward through the right rectus was closed with interrupted sutures of coarse silkwormgut. The rest of the wound was closed in layers with no. 1 tanned catgut. The enterostomy tube was brought out through the outer end of the McBurney incision. The skin was closed with a continuous suture of 00 tanned catgut.

The general anesthetic was given for one hour and fifty minutes, and the operation lasted two hours and ten minutes. The pulse rate was 96 at the beginning of the operation and 120 at the end.

The specimen consisted of the lipoma, which measured 2.5 by 2.5 cm. On the peritoneal surface there was a small projection of the lipoma, but most of its

Fig. 4—Gangrene of the abdominal wall, eight days after the first operation. A loop of bowel is protruding through the gangrenous tissue at the inner portion of the incision.

surface was covered with the mucosa of the intestine (figs. 1 and 2). It grew from the portion of the intestine opposite the mesentery and pushed in the mucous membrane so that most of the tumor was within the lumen of the bowel. It appeared to spring from the submucosa (fig. 3).

The immediate recovery of the patient after the operation was satisfactory. Two days later, a gangrenous area was noted at the tip of the flap that was made by extending the incision along the right rectus muscle from the inner end of the McBurney incision. This affected area was removed with the endotherm knife, and a considerable amount of necrotic material beneath the skin was revealed. The wound was packed with gauze soaked in 2 per cent solution of formaldehyde. It was hoped that this treatment and drainage would be satisfactory to check the gangrene, but it continued along the region of the flap outlined by the two incisions.

Fig. 6.—Temporary repair of the abdominal wall after the gangrenous tissue was excised. The patch from the inner tube and the supporting metal strips were all that retained the intestines within the peritoneal cavity.

The bowels moved well, and the enterostomy tube was removed six days after its insertion. The abdominal contents were prevented from being extruded merely by some of the through-and-through sutures that extended from the gangrenous tissue on one side to apparently healthy tissue on the other. It was obvious that any straining or coughing would soon loosen this slender restraint, and the patient would be disemboweled (fig. 4). The gangrenous area, however, had become so extensive that it was impossible to close the abdominal wall after the gangrenous material was removed even if it had been advisable to do a plastic operation in the presence of infection. The problem was not a simple one. It consisted, first, in checking the gangrenous process and, second, in retaining the intestines within the abdominal wall until the infection could be overcome and some plastic operation

for closure could be done. As the transplantation of a flap at the time was impossible, on account of the size and the locality of the defect and of the presence of infection, and as removal of all the gangrenous area would make the defect still larger, it was obviously necessary to utilize some artificial means of retaining the intestines in the abdominal cavity until the infection could be overcome.

Hertzler<sup>1</sup> showed that certain types of foreign bodies, such as cork, can be placed in the peritoneal cavity under aseptic conditions and will be rather rapidly covered with an endothelial membrane practically identical with the peritoneum. Rubber in certain forms appears to be almost nonirritating to the tissues. Dentists make use of this nonirritability of rubber in forming plates for teeth and in other types of dental work.

As the patient was quite ill, it seemed unwise to attempt to make or obtain any apparatus that might take much time to secure. Consequently, a section of a thick

Fig. 7.—The wound immediately after the removal of the rubber plate and metal supports. The firm exudate which has covered over the intestines should be noted. The intestines in this region were practically free before the rubber plate was inserted. The plate was removed seven days after its insertion.

rubber inner tube from a large automobile tire was cut so that it would be somewhat larger than the proposed defect. On December 22, with the patient under general anesthesia, the gangrenous area was entirely removed with electric cautery. This area followed under the skin well onto the posterior border of the abdominal wall near the spinal muscles and almost to the axilla. Along the peritoneal margins of the gangrenous area there were weak adhesions between the intestines and the healthy peritoneum; as far as possible, these were undisturbed. Throughout most of the wound, the intestines were unsupported. The piece of thick rubber inner tube of an automobile tire was boiled; it was trimmed in the general shape of the defect

1. Hertzler, A. E.: *The Peritoneum*, St. Louis, C. V. Mosby Company, 1919, vol. 1, pp. 251-270.

Fig. 8.—Outline of the flap made twelve days after removal of the rubber plate. In the meantime, a gastrostomy had been done.

Fig. 9.—Appearance of the wound twenty-eight days after the flap was transplanted. In order to relieve tension, adhesive plaster was placed over the flap and sutured to the adhesive plaster on the abdominal wall. In this way the circulation was not disturbed by sutures.

and was fastened into it by insinuating the rubber under the margins of the skin and, when possible, under the margins of the muscle as well. The patch was held with mattress sutures of coarse silkwormgut. To support the rubber, three pieces of metal made from malleable copper retractors coated with silver, with holes drilled in each end, were prepared and placed over the rubber, tucked under the margins of the skin and fastened with silkwormgut sutures (fig. 5). A large drainage tube was put in the posterior extremity of the wound where it led up toward the axilla. The incision toward the axilla was loosely closed with a few interrupted sutures of silkwormgut (fig. 6).

Fig. 10.—Appearance of the abdomen on April 10, 1928, showing the wound almost entirely healed except for a few granulating areas. A few weeks after this, the wound was completely healed. At present there is a small amount of bulging which is easily controlled with an abdominal binder.

The largest piece of necrotic tissue that was removed measured 18 inches (45.7 cm.) in length. It was foul and completely necrotic. Several smaller pieces were also removed.

The patient reacted satisfactorily. Leakage did not occur from the enterostomy wound. The dressings were frequently changed, as there was considerable discharge of pus. Seven days after this operation, the metal pieces and the rubber patch were removed. The intestines were well coated with a thick, fairly firm exudate (fig. 7). It was impossible to secure muscular support for the defect in the abdominal wall, so a pedicle flap was relied on. A long pedicle

flap of skin and subcuticular fat was outlined along the upper margin of the incision with the base posteriorly (fig. 8). This was done in stages so as to throw the vascular supply gradually on the pedicle. Finally, after three operations, the flap was freed, except from its pedicle, and transferred over the raw surface. By undermining the tissues along the inner and lower border of the defect, the skin could be approximated at these points. The flap healed satisfactorily throughout.

The patient, however, developed a sore pharynx, and it was difficult for him to take nourishment. He had been given quantities of dextrose in Ringer's solution intravenously until most of his veins had become unavailable for this. If food was pushed he strangled, and there was great danger of pneumonia. Consequently, on Dec. 30, 1927, sixteen days after the first operation and before the flap had been transferred but while it was being prepared, a gastrostomy was done under local anesthesia, the operation being performed while the patient was in bed. Practically all feeding was then given through the gastrostomy opening. The patient began to improve soon after the gastrostomy. The gastrostomy tube was removed about three weeks later. The wound healed quickly. He was discharged from the hospital on Feb. 23, 1928 (fig. 9).

Figure 10 shows his condition in April, 1928. When heard from a few weeks before this article was written, he was in good general health. There was some bulging of the abdominal wall on the right side, though this was well controlled by a supporting belt. He was attending to his ordinary duties.

#### COMMENT

There are several interesting features about this case. An intussusception in an adult due to a lipoma in the ileum is rare. An intussusception caused by an intestinal tumor is not common, but one caused by a lipoma is extremely rare. Watts<sup>2</sup> reported two cases of intussusception due to tumors—one an adenoma and one a sarcoma—and referred to the literature on the subject. Willis<sup>3</sup> reported three cases of intussusception due to benign tumors of the intestine and also cited references to the literature. Most of these intussusceptions occur in children or infants.

The second unusual feature of the case is the gangrene of the abdominal wall. Instances in which ulceration and certain types of gangrene have followed abdominal operations, particularly when the intestinal tract has been opened, have been fully recorded. One of the most interesting articles is by Brewer and Meleney,<sup>4</sup> in which they described a case of progressive gangrene of the skin and subcuticular tissues following an operation for appendicitis. In some experimental work by these authors, the conclusion was reached that when the

nonhemolytic micro-aerophilic streptococcus and the hemolytic *Staphylococcus aureus* from the patient's wound were injected together into guinea-pigs, rabbits and one dog, almost invariably gangrene was produced, but that when these organisms were injected separately gangrene did not occur. There seems to be a symbiotic function or combination of functions of these two organisms, and without it gangrene does not occur. The streptococcus is found more rarely than *Staphylococcus aureus*, and consequently might be more easily overlooked in routine cultures. Cullen of Baltimore, Christopher of Chicago, Alexander of Philadelphia and Moschcowitz of New York have reported somewhat similar cases.

In this case, however, the gangrene was of a somewhat different type. It proceeded not so much as an ulceration, but as a massive death of the tissues in which the skin and subcutaneous tissues were less extensively affected than the muscles. The smear from the wound showed many gram-negative bacilli, a few short chains of streptococci, a few large gram-positive diplococci, a few large gram-positive bacilli and many gram-positive cocci. Cultures from the wound after forty-eight hours in a blood sugar medium showed many diphtheroid bacilli, many small gram-negative bacilli (colon bacilli), a few short chains of streptococci and many gram-positive staphylococci. Cultures in plain agar showed nonhemolytic streptococci, nonhemolytic staphylococci and *Staphylococcus aureus*. Cultures in dextrose broth showed many gram-positive cocci (staphylococci), a few large gram-positive diplococci, occasional short and long chain streptococci, and many small and large bacilli, both gram-negative and gram-positive. Three cubic centimeters of pure mixed culture was injected subcutaneously into a guinea-pig. The guinea-pig died forty-eight hours after the injection. At necropsy the skin, the fascia and the muscles of the abdominal wall showed beginning gangrene with a foul odor. The kidneys, the liver and the lungs showed signs of active congestion. The peritoneal cavity contained some foul smelling, straw-colored fluid. The culture and smears from the guinea-pig showed the same organisms as those already described.

A partial report concerning a culture from the wound taken by Dr. Frederick W. Shaw, professor of bacteriology at the Medical College of Virginia, on Jan. 10, 1928, is as follows: "Genus, *Klebsiella*. The bacterium was capsulated, gram-negative, nonmotile, with reduced nitrates. There was a thin pedicle on Durham's. It was pathogenic for guinea-pigs. This organism would be classified by Perkins as *Bacterium duodenal* Ford."

Obviously the most satisfactory treatment for this gangrene is removal by the electric cautery. An incision with the knife would doubtless open healthy tissue to this infection and, if made, it should be followed at once by some strong cauterizing agent. The endotherm

knife undoubtedly would be helpful in such cases, but because of the close proximity of the bowel it might be dangerous; so, though the endotherm knife was used in the first limited excision, the regular electric cautery was used in removing the large mass of gangrenous tissue. There is also the advantage of greater heat, which would penetrate deeper.

A third interesting feature is the use of the rubber for temporary support of the abdominal wall. After the gangrenous process, it was obvious that it would be only a short time before the patient would become disemboweled, and merely replacing the intestines in the abdomen without a support would have been of little help. Rubber was selected as a temporary support, as already indicated, because of its nonirritability and because it was readily available. The section from an inner tube proved effective. On the under surface, next to the peritoneal cavity, an exudate membrane rapidly formed. While the exudate was still thick but after the wound was clean, a plastic operation was readily accomplished.

Another feature of some interest is the gastrostomy which was utilized to feed the patient, to avoid bronchopneumonia and to give rest to the throat.

#### SUMMARY

A case is reported in which an operation was performed on an elderly man for intussusception apparently due to a lipoma of the ileum. Massive gangrene of the abdominal wall followed, necessitating excision of the gangrenous tissue and temporary repair of the abdominal wall with a section of an inner tube from an automobile tire. Later, a plastic operation was performed. On account of painful pharyngitis, a gastrostomy was done.

# PRIMARY GIANT CELL TUMOR OF THE PATELLA \*

M. J. KING, M.D.

MOUNT MCGREGOR, N. Y.

AND

G. S. TOWNE, M.D.

SARATOGA SPRINGS, N. Y.

Giant cell sarcoma was apparently first recognized in 1845 by Lebert.<sup>1</sup> Paget,<sup>2</sup> in 1853, and Nelaton,<sup>3</sup> in 1860, described this lesion, and Robin,<sup>4</sup> in 1850, described benign tumors of bones containing large giant cells, which he identified with marrow giant cells. In 1879, Gross<sup>5</sup> analyzed seventy cases of giant cell sarcoma, describing their features and emphasizing their benign nature.

In America, the giant cell tumors were not regarded as malignant until 1910 when Bloodgood emphasized their benign character. In 1920, he<sup>6</sup> reported forty-seven cases in none of which metastasis had occurred. In 1920, Codman<sup>7</sup> established a general registry for bone sarcoma which stimulated interest in tumors of the bone, but the actual etiology and pathogenesis have never been worked out. Codman stated that over a hundred cases of giant cell tumor had been registered without a true case of metastasis. Chatterton and Flagstad,<sup>8</sup> in 1927, reported two cases of giant cell tumor which, although microscopically benign, developed changes suggestive of malignancy. They stated in conclusion: "These two cases, with others reported, suggest that at times difficulty and peculiarity are encountered in diagnosis and behavior of giant-cell tumors." Coley<sup>9</sup> from a study of fifty cases, in nine of which metastasis had occurred, concluded that occasionally a frank giant cell tumor may

undergo changes of a malignant type. In 1927, he<sup>10</sup> reported a follow-up of these fifty cases and included nineteen new ones. He concluded: "Giant-cell sarcoma, or 'giant-cell tumor' as it is designated by most pathologists today, while in the great majority of cases, a benign or at least only locally malignant lesion, should still be classed as a sarcoma since in certain cases it has all the clinical features of a malignant bone tumor causing death by metastases." Cole<sup>11</sup> stated that "giant-cell tumors can be cured by curettement and local recurrence prevented by cauterization of the cavity thus formed with pure carbolic acid followed by alcohol." Stone and Ewing<sup>12</sup> held that rarely, if ever, does a true giant cell tumor metastasize. They said, "There is no satisfactory record of metastasis of a giant-cell tumor in its original form."

Several hundred cases of giant cell tumors have been reported in the literature, a small group of which have been multiple. The latter were considered by Alexander and Crawford.<sup>13</sup> Christensen<sup>14</sup> listed 1,000 cases of tumors of the bone, but recorded only one primary tumor of the patella in this group—a malignant osteogenic type. Thus it is seen that single primary tumors of the patella are extremely rare. Cole,<sup>11</sup> in 1925, reported the first benign cyst of the patella. He found this the twenty-fifth patellar tumor recorded. This series of twenty-five tumors of the patella included all the common tumors of bone, except myxoma. In fourteen of twenty-one of these cases in which information was available, there was a history of trauma. The injury to the patella had occurred from about two months to several years previous to the development of the tumor. There is on record another case of patellar tumor not included in Cole's list of twenty-five. It was reported in 1924 by R. Faltin<sup>15</sup> as a giant cell tumor of the patella. His patient had for five years had a tumor that destroyed the patella. The tumor was enucleated and the cavity scraped out. After a few months there was a regeneration of the patella. Microscopically, it could be ascertained that the tumor tissue, which was rich in cells and contained giant cells, was continuously differentiated into connective or scar tissue which was

poor in cells and did not contain any giant cells. He would not declare the tumor a true blastoma but thought that it was rather a condition belonging to osteitis fibrosa localisata.

The following is the report of a case on the surgical service of the Saratoga Hospital.

Fig. 1.—Section of the tumor showing chronic inflammation and giant cells;  
× 65.

#### REPORT OF CASE

A well developed and well nourished man, aged 19, consulted the surgeon because of a "swollen knee and difficulty in getting about." He said that his illness had begun about two months previously, when he fell and struck his left knee on a sidewalk. He noticed that the swelling and lameness developed soon after the fall. Four weeks before the accident, he had an attack of "septic sore throat," from which he made a complete recovery in two weeks. Physical examination on admis-

sion to the hospital showed the left knee reddened, with considerable swelling and sensitiveness over the patella. The results of the physical examination were otherwise essentially negative. A history of venereal disease or of tuberculosis was not elicited, and the Wassermann reaction of the blood was negative.

A roentgenogram of the knee at this time was reported on by Dr. Earl King as follows: "There is a rarefied condition of the lower two-thirds of the patella

Fig 2—Same section shown in figure 1, with higher magnification;  $\times 210$ .

with destruction of the periosteum and débris about and below the bone. Interpretation—bone tumor, probably giant-cell sarcoma"

On May 8, 1926, an operation was performed, and practically all but the shell of the patella was removed. The cavity was curetted and thoroughly packed with gauze. The wound healed by granulation. The material removed with the curet, which was of a granular, friable, vascular type, was fixed in formaldehyde and sent to the Hegeman Memorial Laboratory for diagnosis.

Microscopic examination of the tissue, which was sectioned in paraffin and stained with Mallory's eosin-methylene blue, showed many fine capillaries with

numerous proliferating endothelial cells intermingled with a spindle cell stroma. In some sections, the bulk of the tumor was composed of small and large giant cells; the large ones contained numerous small separate nuclei and enclosed detritus, blood cells, lipid material and bone spicules. In other foci, the giant cells were less frequent. These cells clearly resembled the foreign body giant cells of Mallory,<sup>16</sup> which he regarded as arising by the fusion of endothelial leukocytes

Fig. 3—Single giant cell showing arrangement of the nuclei and phagocytosed material in the cytoplasm;  $\times 525$ .

The cytoplasm was abundant and sharply defined and stained deeply with acid stain. The nuclei were uniform, without mitoses, and were often clustered near the periphery of the cell. These giant cells resembled osteoblasts and apparently were called into the tissue in response to the presence of foreign bodies resulting from the destruction of bone.

In February, 1928, two years after the operation, the patient was well and was working every day, with normal use of the left knee. There was a linear

16. Mallory, F. B. *J. M. Research* 24:463, 1911.

scar in a perpendicular position over the left patella. The skin was not adherent to the underlying tissues and bone, but there was an indentation on the outer surface of the patella in a line parallel to the scar and directly beneath it. There was apparently a bony exostosis extending from the lower border of the bone, but the

Fig. 4—Roentgenogram taken before the operation, showing rarefaction of the lower two thirds of the patella with destruction of the periosteum.

Fig. 5—Roentgenogram taken two years after the operation, showing a recurrence of the rarefaction and an exostosis extending from the lower surface of the patella.

knee joint functioned properly. Gait was not impaired. Roentgenograms at this time showed an apparent rarefaction in the lower half of the patella and an exostosis extending down the sheath from the lower margin. There had undoubtedly been some local recurrence of the tumor.

## CONCLUSIONS

A case of primary giant cell tumor of the patella is reported. Two years after curettement, the patient was well and did not notice any impairment of function of the knee joint. A roentgenologic recurrence occurred after two years, which should readily yield to curettement and cauterization.

According to the literature, Oddi <sup>1</sup> was probably the first to perform cholecystogastrostomy experimentally in an attempt to discover the effect of bile on gastric acidity. He concluded that bile did not diminish the power of the gastric juice or cause disturbances. Dastre,<sup>2</sup> Cannac<sup>3</sup> and Masse<sup>4</sup> performed similar experiments and arrived at the same conclusions. Mocquot,<sup>5</sup> Wiedemann<sup>6</sup> and Grey<sup>7</sup> performed cholecystogastrostomy on dogs and studied the effect of bile on gastric digestion. Grey also studied the acidity of the gastric juice before and after this operation. They all concluded that bile did not affect gastric digestion in any way, and Grey found that it did not affect the acidity. Gatewood and Poppens,<sup>8</sup> Lehman,<sup>9</sup> Marinelli<sup>10</sup> and Horsley<sup>11</sup> performed chole-

cystogastrostomy on dogs, and studied its effect on the biliary tract and liver. They concluded that the biliary tract always became infected following this operation.

It is apparent from the literature that the use of cholecystogastrostomy is extending; it is now being utilized for many purposes other than irreparable obstruction of the common bile duct. As is well known, diversion of bile into the stomach apparently does not cause digestive disturbances, and in many instances definitely benefits the patient. The clinical evidence that bile is well tolerated in the stomach probably originated with Wickhoff and Angelberger<sup>12</sup> who are given credit for having performed the first anastomosis of this kind on man.

Terrier,<sup>13</sup> Monod,<sup>14</sup> Jaboulay,<sup>15</sup> Montognon and Duchamp<sup>16</sup> each reported a case in which the reaction was favorable following cholecystogastrostomy. Perrin<sup>17</sup> discussed the operation; he attributed the progress in its use to the early experimental investigators, and concluded that the operation is both anatomically and physiologically rational, and easily and rapidly performed. Eichmeyer<sup>18</sup> and Kehr<sup>19</sup> reported many favorable cases of cholecystogastrostomy from the clinic of Professor Hans Kehr of Holberstadt. Jacobson<sup>20</sup> and Erdmann<sup>21</sup> pointed out that this operation should be the one of choice whenever it became necessary to short-circuit the bile, because of the lessened likelihood of ascending infection of the biliary tract and because the digestive function of the bile and the bile salts was preserved. White<sup>22</sup> reported three cases in which

the operation had been used successfully and pointed out the simplicity of technic and the absence of danger of ascending infection.

Babcock<sup>23</sup> and Heyd<sup>24</sup> recommended wider use of cholecystogastrostomy and both believed the operation to be a rational one for gastric ulcer. Babcock advocated the anastomosis of the gallbladder directly into the ulcerated area as a substitute for gastro-enterostomy; he also believed the operation to be preferable to drainage of the gallbladder.

Mayo,<sup>25</sup> Moore,<sup>26</sup> Ralphs,<sup>27</sup> Downes,<sup>28</sup> Stretton,<sup>29</sup> McNealy<sup>30</sup> and Murdy<sup>31</sup> reported favorably on the use of cholecystogastrostomy in the presence of irreparable obstruction of the common bile duct due to the malignant lesions, stricture or other causes. Murdy suggested that the operation could well be used in place of cholecystectomy for infection of the gallbladder without stones, or for cholangitis with or without stones.

DuBose<sup>32</sup> reported favorable results in many cases of cholecystogastrostomy. He recommended much wider use of the operation to include cases of perforated gastric and duodenal ulcers, perforation of the gallbladder and obscure chronic or intermittent jaundice. He did not believe there was danger of infection of the biliary tract and liver following this operation. Deaver<sup>33</sup> stated that cholecystogastrostomy was a better operation than drainage, for it prevented the loss of bile salts and fluids. Frenkel<sup>34</sup> treated twenty-one patients with peptic ulcer by this operation. He noted a decrease in the total and free acid content after

the operation and considered this to be the therapeutic factor. Braithwaite<sup>35</sup> and Nazarov<sup>36</sup> reported cases of peptic ulcer in which the reaction was favorable following cholecystogastrostomy. Nazarov reported a constant decrease in gastric acidity following this operation. Villard and Richer<sup>37</sup> preferred cholecystogastrostomy above other methods of anastomosis because of the ease of technic and the lack of digestive disturbances. Muller<sup>38</sup> presented case histories in which this operation had been performed successfully. Walters<sup>39</sup> pointed out that the operation is most useful in cases of obstructive jaundice due to stricture of the common bile duct, pancreatitis or carcinoma of the head of the pancreas. Weinberg, Wallin and Binger<sup>40</sup> reported a case of cholecystogastrostomy in which recovery was uneventful. Fifteen days after the operation chemical tests of the gastric acidity were found to be negative. To explain this result, the operation was performed on dogs, and specimens of the gastric contents were collected through gastric fistulas. They did not find a change in acidity. Postmortem examinations of the dogs showed infection of the gallbladder and abscesses throughout the liver.

#### METHOD OF RESEARCH

Two series of six dogs each were studied. The animals were normal and healthy and weighed between 7 and 10 Kg. Prior to operation, numerous analyses of the gastric contents were made on all of the dogs in the first series to establish a normal curve of the total and free hydrochloric acid and the total chlorides. Fractional gastric analysis was carried out. The specimens of the gastric contents were removed from the stomach at intervals of fifteen or thirty minutes by means of a large stomach tube and a suction apparatus. The dogs quickly become accustomed to the tube, and do not manifest discomfort from its use. After a few days, if the dog has been gently handled and trained, he will not have the slightest psychic disturbance which might upset gastric digestion.

For the test meals raw horse meat (ground three times) was used. The standard meal was 80 Gm. of meat thoroughly mixed with 250 cc. of water. It was found that such a meal could be withdrawn through the stomach tube readily, and that it did not unduly prolong the period of gastric digestion. The dogs were placed on a fast for twelve hours before the test meal was placed in their cage, and it was found that healthy dogs would eat it immediately. Samples of the gastric content were then removed every half hour until free acid appeared, after which

the samples were removed every fifteen minutes until the free acid disappeared. The free and total acid was titrated against tenth normal sodium hydroxide, dimethylamidoazobenzol and phenolphthalein being used as indicators. The total chlorides were determined by the Folin method.

Röntgen-ray and fluoroscopic studies of the emptying time of the stomach before operation were also carried out in dogs of the first series. Fifteen grams of barium per kilogram of body weight was mixed with an equal amount of condensed milk and acacia. A roentgenogram was taken immediately on ingestion of the motor meal to determine the normal outline of the stomach. The emptying process was then watched under the fluoroscope, and when the stomach appeared to be empty, another roentgenogram was taken. Usually a third picture was taken from a half hour to an hour later.

After completion of the preliminary studies of the dogs in the first series, cholecystogastrostomy was performed under full ether anesthesia with strictly aseptic technic. The suture method of anastomosis was used in all cases; clamps were not used at any time. The technic is essentially the same as that in gastroenterostomy by the suture method. In most cases the approximation of the gallbladder and the stomach was easily accomplished, and the anastomosis did not result in undue tension on the gallbladder. The common bile duct was doubly ligated and incised in each case.

Chemical changes were not observed in the second series of dogs, but the same operation was performed as in the first series. The purpose of the second series of experiments was to determine whether or not pathologic changes occurred in the biliary tract and liver following this type of operation. After the animals had recovered from the operation completely they were returned to their normal diet and conditions of living for varying periods. Exploration was then performed, and sections of the gallbladder, liver and stomach were removed for microscopic examination.

In the first series, two sites of anastomosis between the gallbladder and stomach were selected. In three animals, the gallbladder was anastomosed to the pyloric segment about 2 cm. above the pyloric valve and midway between the lesser and greater curvatures; in the other three, the gallbladder was anastomosed to the fundus of the stomach midway between the lesser and greater curvatures. This was done to prevent any possibility of the bile being swept out of the stomach before it was thoroughly mixed with the gastric contents.

After sufficient time had been allowed for complete recovery from the operation and satisfactory healing of the abdominal wound, fractional gastric analysis was repeated on each dog in the first series. It was customary to allow from ten days to two weeks to elapse before these chemical studies were repeated. Thereafter, at least one complete fractional analysis was made each week for a month and from then on at longer intervals.

The emptying time of the stomach was studied after operation by the same technic as that used before operation.

## RESULTS

All the dogs recovered from the operation, and the wounds healed by first intention. Without exception, the dogs remained in excellent condition and gained weight on a diet of milk and syrup.

The normal curves for the free and total acid and total chlorides before operation were somewhat as follows:

The first sample removed from the stomach did not show free acid but total acid of from 20 to 25, and total chlorides of about from 70 to 80 mg. chlorine for each 100 cc. Samples were removed every half hour until free acid appeared, usually at the end of an hour or an hour and a half. By the time free acid appeared, the total acid had reached from 80 to 100 and the total chlorides from 180 to 240 mg. chlorine for each 100 cc. After the appearance of free acid, samples were removed every fifteen minutes until it disappeared. The free acid was found to rise from 20 to 60, and then to decrease in a gradual curve. After operation, the curves were essentially the same with the exception that free acid usually appeared more quickly, and the total chloride curve usually rose higher.

The postoperative studies of the chemical changes in the first series of dogs showed free and total acid to be present in essentially the same

*A Synopsis of the Protocols of the Six Dogs in the First Series*

degree as before operation. In every case, there was a slight rise in the amount of total chlorides after operation. Some dogs showed more free and total acid after operation than before; others showed slightly less, thereby indicating that this slight variation is insignificant. As might be expected, the degree of biologic variation in this type of work is considerable; thus the curves for total acid and free acid on normal dogs were found to vary as much as 10 or 15 on different days. A dog was not found who showed free acid at one time and not at another, but dogs without free acid when given the standard meal consistently showed the same result. As the dogs selected for this experiment secreted much free acid, and since enough analyses had been performed preoperatively to give an accurate curve of normal gastric acidity, it seems justifiable to conclude that the bile did not have any effect on this function. The accompanying table shows a synopsis of the protocols of the six dogs in the first series. Figures 1 and 2 are typical of the preoperative and postoperative studies of the chemical changes.

It was noted that every sample aspirated postoperatively was heavily stained with bile. The bile was easily apparent macroscopically, and its presence was confirmed repeatedly by the microscope and the van den Bergh test. There can be no doubt that bile was getting into the stomach and was mixing with the gastric contents. In spite of this, some of the most heavily bile-stained samples showed the greatest amount of free acid.

Fig. 1.—Studies of gastric digestion before and after cholecystogastrostomy. The height of the curves for total acid and free acid is essentially the same after operation as before. The curves for total chlorides are practically identical.

Fig. 2.—Studies of gastric digestion before and after cholecystogastrostomy from another dog in the first series. The free acid appears half an hour earlier after operation, and the height of the curves is identical. The total acid curve is not so high after operation as before, but the variation in all these curves is well within normal limits.

The emptying time of the stomach was not changed by the operation. Immediately after operation the emptying time seemed accelerated, but after the dog had fully recovered, there was essentially no change. One dog, that had apparently recovered entirely, died suddenly thirty-two

days after operation. Fortunately, however, three complete postoperative studies of gastric digestion had been made. At postmortem examination, the anterior surface of the liver was found to be studded by multiple grayish spots having the gross appearance of miliary abscesses. The diaphragm was firmly adherent to the right lobe of the liver, and when this was removed an abscess about 2 cm. in diameter was found. The wall of the gallbladder was thick and grayish. The lungs were

Fig. 3.—Section of the wall of the gallbladder from a dog in the first series, showing marked thickening by fibrous connective tissue and heavy infiltration of large and small lymphocytes.

markedly congested and showed evidence of patchy consolidation. There was no evidence of peritonitis, and healing had taken place at the point of anastomosis without leakage or infection. Microscopic examination of sections taken from the liver revealed acute purulent hepatitis, chiefly periportal. The bile ducts did not show evidence of inflammation; their epithelium was intact, and there was only slight fibrosis around the walls. The wall of the gallbladder was thickened by an increase in fibrous con-

nective tissue but did not show evidence of acute inflammation. Sections of the mucosa of the stomach showed slight round cell infiltration, but the epithelium was intact. The cause of death was attributed to acute purulent hepatitis with abscess formation and secondary bilateral bronchopneumonia (figs. 3, 4 and 5).

The dogs in the second series were explored at varying periods after the first operation, and sections were removed from the gallbladder, liver

Fig. 4.—Section of liver from a dog in the first series, showing acute purulent hepatitis with marked destruction of the cells of the liver.

and stomach, for microscopic examination. In all the dogs in this series, regardless of the time since operation, inflammatory changes developed in the liver and gallbladder (figs. 6 and 7). These changes varied from slight round cell infiltration with replacement by fibrous connective tissue to acute purulent inflammation with extensive destruction, necrosis and abscess formation. In some of the dogs in which exploration was done a short time after operation, the gallbladder and liver appeared

unchanged grossly. When sections were made and examined, however, definite pathologic changes were found.

#### COMMENT

The results obtained from the experiments on the first series of dogs verify those of other investigators. It should be noted, however, that

Fig. 5.—Section of the liver from a dog in the first series, showing acute purulent hepatitis with replacement by fibrous connective tissue in an attempt at healing.

the experiments were performed on dogs with intact gastric mechanism. The technic of performing fractional gastric lavage on dogs as worked out by McCann<sup>41</sup> obviates the necessity of resorting to surgical measures on the stomach in order to obtain the gastric samples. The Pavlov pouch has been used for this type of experimentation but is probably not physiologically perfect, since a large portion of the stomach is separated

41. McCann, J. C.: Personal communication to the author.

into the formation of a pouch. This, in all probability, disturbs the secretory and motor activity of the stomach and may result in a certain amount of independent activity of the stomach apart from the pouch. There can be no doubt that in performing the operation a large part of the nerves going to the pouch are injured. The coordinating mechanism is consequently impaired.

Fig 6—Section of the wall of the gallbladder from a dog in the second series, showing marked thickening and round cell infiltration

Clinically, it is apparent that the operation of cholecystogastrostomy has been gaining favor not only as a means of side-tracking the bile in the presence of irreparable obstruction of the common bile duct, but also as a means of treating lesions as follows: (1) chronic peptic ulcers, (2) hyperacidity with pylorospasm, (3) perforated gallbladders, (4) acute pancreatitis and (5) diabetes in the young with symptoms of biliary obstruction. It may also be used as a substitute operation for cholecystostomy and cholecystectomy. The operation has been recom-

mended, not only because of the ease and rapidity of the technic in comparison with that of gastro-enterostomy and partial resection, but also because of the belief that the bile would actually tend to neutralize the gastric contents. It has been shown many times that the introduction of bile into the stomach does not result in disturbances of digestion. I am in entire agreement with this conclusion. The dogs operated on did not show evidence of gastric disturbance at any time afterward. Many

Fig. 7.—Section of the liver from a dog in the second series, showing periportal round cell infiltration with increase in fibrous connective tissue.

... reports are at hand concerning the excellent results obtained when the operation was used in cases of gastric ulcer or hyperacidity. The invariably offered explanation for these results has been that the bile caused neutralization of gastric acidity, thus allowing the ulcer to heal. The results obtained in this and other experiments, however, have definitely shown that bile does not have any effect on the acidity of the stomach.

The results in the second series of experiments indicate that infection of the biliary tract and liver is the rule following this type of operation. The severity of the infections varied from only slight round cell infiltration to definite localized and miliary abscesses throughout the liver. Most of the dogs appeared to be in good health, but at exploration or necropsy varying degrees of infection were noted. In spite of the assertions to the contrary, I believe that the gastric contents enter the gallbladder in most cases; in support of this may be mentioned the presence of *Ascarides* in the gallbladder similar to those found in the stomach and intestine.

Clinical reports of the results following cholecystogastrostomy for ulcer of the stomach and hyperacidity without ulcer led to the conclusion that there is marked improvement in these patients with disappearance of most of their symptoms. Since it has been definitely shown that it is not the bile in itself which is causing the improvement, the question arises why such results are obtained. It is suggested that the attachment of the gallbladder to the stomach may slow and control gastric peristalsis mechanically, much the same as the speed of a motor is slowed by back gearing, thus accounting for the improvement.

Clinical literature on cholecystogastrostomy is lacking in postmortem reports in cases in which this operation was performed; so it is apparently not known whether or not infections of the biliary tract and liver develop. Wangensteen,<sup>42</sup> however, reported cholangitis following cholecystoduodenostomy in a case in which the procedure was performed for a malignant lesion of the head of the pancreas causing obstructive jaundice. The patient lived a little more than a year, and during that time it was necessary to drain the hepatic ducts several times for relief from symptoms.

At necropsy the diagnosis of cholangitis following cholecystoduodenostomy was confirmed. The absence of symptoms in the early stages is not an indication to the contrary, for the dogs in the second series all appeared perfectly well, and most of them gained in weight. The fact that infection developed in each of these dogs would lead to the assumption that the same process may occur in man. There can be no question that cholecystogastrostomy is the operation of choice in cases in which it becomes necessary to short circuit the bile because of irreparable obstruction of the common bile duct. This operation is justified in the presence of a malignant lesion of the duct causing obstruction, carcinoma of the head of the pancreas, stricture of the common duct and similar conditions. From the results of experimental work, however, it is ques-

---

42. Wangensteen, O. H.: Cholangitis Following Cholecystenterostomy, Ann. Surg. 87:54, 1928.

tionable whether one should employ this operation in the treatment of patients with ulcer, hyperacidity or many of the other diseases for which it is advocated, in view of the great probability that disease of the liver and biliary tract will result.

#### SUMMARY

The literature pertaining to cholecystogastrostomy from both an experimental and a clinical standpoint is reviewed.

An experimental study of cholecystogastrostomy was undertaken to determine the effect of bile in the stomach on gastric secretion and motility, as well as the possibility of infections of the biliary tract and liver. Twelve normal dogs were studied in two series of six dogs each. In the first series, gastric digestion was studied by the McCann method of fractional gastric analysis for dogs. The emptying time of the stomach was also determined by means of the barium meal and the fluoroscope. Cholecystogastrostomy was then performed with double ligation and incision of the common bile duct. Following recovery, fractional gastric analyses were again made to determine whether the bile had any effect on gastric acidity. The results in the first series showed definitely that bile did not have any effect on the acidity of the stomach. The post-operative emptying time was essentially the same as the preoperative.

In the second series of dogs, gastric analyses were not made, but the same type of operation was performed as in the first series. The dogs were allowed to live under normal conditions for varying lengths of time and were then operated on to determine whether pathologic processes were developing in the gallbladder and liver. The results of the observations in the second series led to the conclusion that infections of the biliary tract and liver always occur following cholecystogastrostomy. It is suggested that the absence of clinical evidence of such infections does not preclude the possibility that pathologic changes in the biliary tract and liver are occurring in patients who have been subjected to cholecystogastrostomy.

## KIDNEY

*Surgical Technic.*—Pérard<sup>1</sup> stated that fistulas are rather common following operations on the kidney and renal pelvis. To avoid a pus-producing fistula after operation on tuberculous kidneys, the ureter should be anchored to the skin. If a fistula should occur, it may be destroyed by the use of cauterizing agents. Certain fistulas cause large, deep, pus cavities which must be opened and healed by the use of tampons. Fistulas following ordinary pyogenic infections are quite rare and generally, if they do not respond to treatment, are due to the presence of a foreign body. Fistulas due to perinephritic abscesses continue if drainage is poor. Treatment consists of opening the abscess wide and breaking down any pockets that may be present. Urinary and pus fistulas can then persist only if there is a stone in the kidney, pelvis or ureter, or if there is ureteral obstruction in cases of hydronephrosis.

Urinary fistulas persist after nephrectomy if a certain amount of parenchyma remains, or if there is a vesico-ureteral backflow. Treatment in the first case consists in complete removal of the remaining renal tissue, and in the second, in either the use of a retention catheter or fulguration of the ureteral orifice. If the last two methods fail, complete resection of the ureteral stump should be undertaken. If this fails, the bladder must be freed on the normal side by ureterostomy. Fecal fistula usually occurs only after intestinal injuries. If the duodenum is affected, the patient usually dies of inanition unless gastro-enterostomy or cholecysto-enterostomy is carried out.

Kaïris<sup>2</sup> stated that certain present-day surgeons, of whom Marion is a well known example, have done away, for the most part, with sutures in performing pyelotomy and ureterotomy. In a series of cases in which operation was performed in Joseph's clinic good results were obtained by not using sutures. In all of the cases there was urinary drainage for only a few days, and in three cases of pyelotomy there was none. These clinical facts were tested experimentally with dogs in which either a slit was made in the ureters or a small piece of the wall cut away and the wound left open. The sutureless wound healed as well as in the clinical cases. The scar was constantly quicker in forming, and after from two to three weeks it could be felt only as a small, firm line. Stricture was not noted.

Beer<sup>3</sup> stated that one of the difficulties in renal surgery is to decide whether the second kidney is really adequate. It is known that normal, although inadequate, secretion can take place from a hypoplastic kidney. The value of various tests can be experimentally studied on a kidney that has been nephrotomized and sutured. Beer examined one patient repeatedly following complete nephrotomy to determine whether that kidney was deprived of any functional ability. The percentage of urea concentration, the indigo carmine concentration and the phenolsulphonphthalein output were only slightly changed from that of the normal opposite side. About a month later, a differential phenolsulphonphthalein test was made, and the side operated on compared with the one not operated on as 45:65. Ten months later, the phenolsulphonphthalein was concentrated in six minutes on both sides. The ratio was 4:7.

Patel and Peycelon<sup>4</sup> reported a case of abdominal nephrectomy in which the vena cava was injured and consequently ligated. The patient recovered uneventfully. Procedures generally resorted to in such cases, such as compression, clamping, ligation and suture, were discussed. Patel and Peycelon preferred ligation as it is easy and quick and, if the hemorrhage has not been too marked, it is generally followed by good results. In cases of lateral contusion, a suture would be preferable. Various factors must be considered, such as the condition of the patient, the extent and site of the wound, the degree of hemorrhage and the accessibility of the vein. The authors stated that the anterior route is desirable in operating on large kidneys. Laceration of the vena cava could be repaired only with difficulty through a lumbar incision, and as

laceration is usual in operating on a large pyonephrotic kidney, the kidney should be removed anteriorly.

Hunt<sup>5</sup> reviewed approximately 1,550 major surgical lesions of the kidney and ureter in patients operated on at the Mayo Clinic from 1922 to 1926. There were 916 nephrectomies, 127 (13.8 per cent) of which were for malignant lesions, with ten deaths (7.8 per cent).

In the upper part of the urinary tract, the lesions found in lithiasis comprised 55 per cent of the lesions for which major operations on the kidney and ureter were necessary and 49 per cent of the surgical lesions of the kidney. Single stones are usually situated in the pelvis and are readily accessible by pelviolithotomy. A bilateral operation is not indicated in all cases of bilateral renal lithiasis. In the absence of acute symptoms but with distinct evidence of marked difference in the amount of renal injury due to the presence of stones, it has seemed best to operate first on the kidney with the better function, in order to take advantage of the function remaining in the poorer kidney during the acute stages following operation. Nephrectomy was necessary in 229 (33 per cent) of the total number of cases of renal lithiasis. It is clearly indicated when the kidney is functionless as a result of calculi or when there is pyonephrosis or marked infection. There were five deaths following operation for renal stone and extensive infection. Conservative operations of pelviolithotomy and nephrolithotomy were performed in 440 cases and the combined operations in 417 cases. Pelviolithotomy is the operation of choice; it is least destructive to renal tissue. Stones were removed in 84 per cent of the cases by pelviolithotomy. Nephrolithotomy is usually done for stones in the ends of the calices.

Localization of shadows at operation is important in order to assure removal of all multiple stones. Braasch and Carman devised a method of fluoroscopic examination with the kidney elevated out of the wound at the operating table, which has proved valuable in the detection of small particles of stony material and has afforded reasonable assurance of complete removal of all stones before the conclusion of the operation. Fluoroscopy at operation has made possible the conservative operation of pelviolithotomy for multiple stones in cases in which nephrectomy was formerly necessary.

Seventy per cent of ureteral stones requiring surgical removal were situated in the lower third of the ureter. Hunt reiterated the importance of accurate localization of ureteral stones before operation. Ureteral and renal lithiasis on the same side occurred in fifteen cases, in ten of which simultaneous pelviolithotomy and ureterolithotomy were

---

5. Hunt, V. C.: The Upper Urinary Tract; a Consideration of Its Surgical Lesions, *Northwest Med.* 27:213, 1928.

performed. In five cases complete nephro-ureterectomy was necessary. In twelve other cases, a ureteral stone had been productive of pyonephrosis in seven and of hydronephrosis in five, making necessary nephrectomy and partial ureterectomy to a point below the ureteral stone.

Associated tuberculous lesions were found in 80 per cent of cases of surgical renal tuberculosis. In the absence of general contraindications, this should not deprive the patient of the benefit to be obtained from removal of the major tuberculous lesion, if it is in one kidney. The low primary mortality rate following nephrectomy for unilateral renal tuberculosis justifies the operation, even if there is moderate pulmonary involvement. Diffuse miliary tuberculosis is considered a contraindication to nephrectomy. Renal tuberculosis formed the indication for nephrectomy in 258 cases, 28 per cent of the various conditions for which nephrectomy was necessary. There were six deaths, a mortality rate of 2.3 per cent. Indolent healing of the wound and a temporarily persisting sinus at times follow nephrectomy for renal tuberculosis. The ureter is usually thickened and dilated and, if not actually tuberculous, presents definite ureteritis, which has in many instances been the cause of a persisting sinus. Various methods of treating the ureter, such as injection of its lumen at the severed end with pure phenol, actual cautery sterilization of the stump, and bringing it to the surface of the skin and threading a tube over its end to carry subsequent drainage to the surface, have been advocated to prevent a postoperative sinus of ureteral origin. Walters showed that ligation and sterilization of the severed end of the ureter with the actual cautery is the most satisfactory method of treatment; a sinus persisted only temporarily in 25 per cent of the cases. A sinus of ureteral origin in the absence of a ureteral stricture rarely requires ureterectomy. It is inadvisable to insert drainage tubes after nephrectomy for renal tuberculosis, as it invites secondary infection, and a postoperative sinus develops with slow healing of the wound. Closure of nephrectomy wounds without drainage results in primary healing in a high percentage of cases.

*Anomalies.*—Alessandri<sup>6</sup> reported a case in which there was an anomalous orifice in the urethra of one of two left ureters and also a duplication of the right ureter and a bilateral double pelvis.

At operation the left kidney appeared larger than normal. It was composed of two parts separated by a groove. The superior segment, representing a third of the whole kidney, was composed of a thin layer of kidney substance and by a large dilated pelvis and ureter. The

---

6. Alessandri, Roberto: Bilateral Double Pelvis and Ureter with Anomalous Opening of the Superior Left Ureter into the Urethra; Congenital Ureteral Incontinence, *Surg. Gynec. Obst.* 47:111, 1928.

inferior part of the kidney was apparently normal. Each section had its own vessels. The vessels to the upper segment were ligated and cut and the halves of the kidney separated. A V-shaped segment was removed from the lower half to permit good approximation of the sides of the incision. Recovery was uneventful.

[ED. NOTE.—Heminephrectomy such as reported by Alessandri has been carried out in comparatively few cases. On first thought, resection of the diseased segment of a double kidney seems to be a formidable procedure. When conditions are favorable, however, it does not offer any great technical difficulties and is followed by favorable results. The opportunities for the operation are limited, and the anatomic conditions are often not recognized. With proper suturing, postoperative hemorrhage should be negligible.

Removing a V-shaped segment from the lower portion in order to facilitate the closure of the wound was first practiced by Albarran in resecting the commissure of a horseshoe kidney. If infection remains in the tissues, a sinus may persist indefinitely and reopen at intervals. Often in these cases the groove which Alessandri mentioned is so deep that it almost bisects the renal mass. In other cases the capsule projects into the mass, causing an avascular area in the region of the groove or dividing point.]

MacKenzie and Hawthorne<sup>7</sup> reviewed the literature and reported six cases from the urologic service of the Royal Victoria Hospital at Montreal of developmental defects of the kidney with absence of function on one side. They described this condition as unilateral renal aplasia.

In the complete absence of the kidney, the renal bud apparently does not form from the wolffian duct. MacKenzie and Hawthorne added one case to the 350 or 360 cases of this type thus far reported.

A defect at a later period of developmental life would bring about the condition frequently seen if the kidney is absent, that of normal genital formation with a normal bladder and ureteral orifices, but with a short rudimentary ureter, which may or may not be patent. The short rudimentary ureter is fairly common. In many of these cases there may not be the slightest evidence of renal tissue, and this would indicate lack of development of nephrogenic tissue. A defect arising at a later period would leave a more perfectly formed kidney in a state of hypoplasia and without function.

The sole functioning kidney, under the load of carrying all of the excretory function, is often subject to injury by nephritis, calculus or

---

7. MacKenzie, D. W., and Hawthorne, A. B.: Unilateral Renal Aplasia, *Surg. Gynec. Obst.* **46**:42, 1928.

by infection. A more than normal percentage of persons with congenital solitary kidney die of renal complaints.

Three of the six cases reported were in males and three in females. The left side was affected in four cases, which agrees with the statistics from the cases in the literature. The symptoms which cause the patient to come for investigation are usually on the side of the remaining kidney, although in three cases pain was complained of on the side of the aplastic kidney. In all but one case, the frequency of urination, burning and pyuria were due to infection in the solitary kidney.

The bladder was symmetrical in five cases, and one case showed absence of the left ureteral orifice and the left half of the trigonal ridge. The right ureteral orifice was absent in one case complicated by vesicovaginal fistula, and in another case the left orifice was scarred and gaping as the result of an inflammatory lesion. The ureter on the side of the aplasia varied. In one case there was no evidence of an orifice. In three cases there was a short rudimentary ureter, which was patent for some distance. In two of these it ended blindly, and in one it was continued as a fibrous cord attached to the aplastic renal tissue found in that region. In two cases the ureter was present throughout and was dilated, thickened and filled with purulent material; in each case, it showed a stricture in its lower portion. Evidences of renal tissue were found in five of the six cases. This varied in type from masses of fat and fibrous tissue containing nests of epithelioid cells, small cysts and rudimentary glomeruli, to definite pelves (two cases) surrounded by a shell of tissue composed of connective tissue, tubules and a few glomeruli, many of which had been replaced by connective tissue.

Aplastic kidneys are functionless, although there is sometimes unexplained pain on the side of the aplasia. Operation and removal of the rudimentary kidney relieved the pain in two instances.

[ED. NOTE.—The lesion of unilateral renal aplasia is doubtless more common than is generally believed. The condition bears some similarity, if not an embryogenetic relationship, to duplicated kidneys and polycystic disease, although in the cases mentioned, only conditions of unilateral aplasia in which the kidneys are more or less complete and functionless are considered. As a urologic problem, diagnosis is of the utmost importance, and the condition is to be borne in mind in differentiating occluded tuberculosis, atrophic pyelonephritis and postoperative or traumatic occlusion of the ureter.]

Papin<sup>8</sup> explored the right kidney of a patient, aged 21, who was suffering from pyelonephritis with renal retention. He found the kidney to be large, ptotic and malformed; its hilum faced anteriorly. The kidney had two vascular pedicles, an inferior accessory pedicle and a

---

8. Papin, E.: Un cas d'uretère borgne, *Presse méd.* 42:665, 1928.

larger superior pedicle. The latter, before reaching the kidney, passed over a large elongated sac, which ended in a culdesac at its superior extremity. This sac was a duplicate ureter closed at both ends, the lower portion terminating at the bladder. This ureter, as well as the remaining ureter and attached kidney, was removed. Cystoscopic examination showed only two normal ureteral orifices; it had been impossible, either by cystoscopic examination or by the ureterscope, to identify an orifice corresponding to the second ureter.

*Ptosis and Perinephritis.*—Scholl<sup>9</sup> stated that peritoneal tension due to a displaced kidney may at times obstruct the bile ducts and initiate a chain of symptoms such as pain, nausea and jaundice, which are indistinguishable clinically from true gallbladder disease.

The patient, a man, aged 55, had a fall which dislodged the kidney. He had had several attacks of severe pain in the region of the gallbladder associated with jaundice. Urologic examination revealed a large infected hydronephrotic sac containing stones on the right. The removal of this kidney caused all symptoms of gallbladder trouble to disappear.

During the course of the examination, the insertion of a ureteral catheter for drainage of the kidney caused immediate cessation of symptoms, including diminution of jaundice. Later the catheter was deliberately removed to see if this would cause a return of symptoms. A prompt return of pain and jaundice suggested a close causal relationship. A second ureteral catheterization again afforded relief and was continued until the time of the operation. Ureteral drainage not only gave the patient relief from symptoms but, by decreasing the size of the kidney and draining out most of its infected contents, the operative removal was facilitated and the possibility of contamination of the surgical field reduced.

The upper abdominal pain associated with secondary biliary disease is rarely as severe as that which occurs in acute gallstone colic, and it is usually relieved if the patient is placed in the prone position. The symptoms resulting from movable kidney are most common in thin, young women, and differ from those in the fleshy type of woman usually suffering from disease of the gallbladder. Jaundice is usually mild, intermittent and of short duration.

*Tumors.*—Judd and Simon<sup>10</sup> reported a case of angioma of the kidney. The literature on this subject is limited to single case reports. They reviewed eleven cases that are apparently authentic, and they reported one case of their own.

---

9. Scholl, A. J.: Jaundice Due to Movable Kidney, California & West. Med. 29:87, 1928.

10. Judd, E. S., and Simon, H. E.: Angioma of the Kidney, Surg. Gynec. Obst. 46:711, 1928.

The patient, a woman, aged 57, had been having attacks of hematuria for twenty years. The bleeding was at times extremely abundant and associated with renal colic on the left side. Cystoscopic examination demonstrated that there was less excretion from the left kidney than the right; the left pyelogram was normal. In spite of a negative cystoscopic examination, the left kidney was explored and found to contain many dilated blood vessels in the superior pole. It was removed. A tumor 1.5 by 2.5 cm. was found in the cortex at the upper pole.

Microscopically the glomeruli were moderately sclerotic, especially in the region of the tumor where there was also moderate round-cell infiltration. The tumor was sharply demarcated from the renal tissue, but there was no evidence of encapsulation. It was composed of a network of capillaries and endothelial-lined spaces, filled with blood. The blood cells were for the most part well preserved but, in some areas, they had disintegrated, and considerable blood pigment was deposited throughout the tumor.

A distinction should be made between true angioma and other blood-containing tumors which may appear in the kidney. Carcinoma in which the spaces have become packed with blood cells is most likely to lead to confusion. Hemorrhagic cysts of the kidney are large and angiomas are small.

Cahill and Gile<sup>11</sup> reported a case of a large papillary carcinoma of the kidney. The patient, a negro, did not appear to be ill. Examination of the abdomen revealed a huge mass filling the entire left side and extending across the median line. A diagnosis was made of cystic kidney, and at operation a huge cystic mass was removed through a left rectus incision. Before the mass could be delivered, 6 liters of fluid was aspirated; more than 2 liters remained and was removed with the tumor. The patient recovered readily following operation and went home on the seventeenth day; the wound was firmly healed. The diagnosis was carcinoma of the kidney (papillary type).

Bumpus<sup>12</sup> reported a case of recession of pulmonary metastasis in a case of hypernephroma following nephrectomy. The kidney contained a large hypernephroma which filled the pelvis and extended into the pedicle and into the perirenal fat. A roentgenogram of the chest disclosed multiple metastatic areas in both lungs. Five months later the patient was feeling quite well, and another roentgenogram showed that all evidence of the former metastatic nodules had disappeared. Four years after removal of the primary growth, the lungs were still clear and there were no other signs of metastasis.

12. Bumpus, H. C.: The Apparent Disappearance of Pulmonary Metastasis in a Case of Hypernephroma Following Nephrectomy, *J. Urol.* 20:185, 1928.

Ljunggren<sup>13</sup> stated that he believed that the vagaries of time and appearance of hematuria in cases of renal tumors must be sought in the fact that the initial invasion by the tumor is often found in the most distal portion of a calix. These calices are frequently more or less dislocated, lengthened and compressed by the tumor, as is demonstrated in the pyelogram. Occasionally they may be entirely surrounded by the tumor. One such calix may easily be blocked by a small blood clot, so that blood does not enter the pelvis, and the urine clears suddenly. Such a process may explain a sudden increase in the size of the tumor by inward bleeding. The obstruction of a calix may become permanent, and a year or so later another attack of hematuria may occur, probably due to erosion of the tumor into another calix.

Schönheimer<sup>14</sup> stated that if hypernephroma originates from the suprarenal cerebroside, a chemical compound should be found as in tumors coming from the kidney. In 1909, Rosenheim and Tebb demonstrated its presence in the kidney.

Demonstration in a hypernephroma was carried out as follows: A large tumor weighing 2 Kg. was extracted for two months with acetone. The powder was completely extracted with ether and then treated with boiling alcohol. From the alcohol extract, a crystallized mass was obtained which was broken up with 1.5 per cent sulphuric acid. The galactose was isolated from the split end-product. It was identified in the form of its o-toluene-hydrazone.

Derman<sup>15</sup> reported a case of renal tumor in a man, aged 46. The growth was grayish-yellow and of cartilaginous consistence, with a smooth cross-cut surface; it was embedded in the parenchyma and renal pelvis. The original nidus of development seemed to be from the parenchyma, that is, the malpighian tubules; it then apparently invaded the adjacent tissues and metastasized into the epididymis. It is possible that the secondary growth may have reached the epididymis through the blood stream by means of the left renal or the spermatic artery. The growth appeared to be associated with much scarring and shrinking of the underlying tissues. The ureter was obstructed, causing hydronephrosis. Microscopic examination revealed a new growth of epithelial strands of cubical and cylindric cells. The diagnosis was "carcinoma scirrhuso-gelatinosum nodosum." The metastatic growth in the tail of the epididymis was similar to the original growth.

*Cystic Disease.*—Carson<sup>16</sup> reported four cases of solitary serous cysts of the kidney, adding these to the 141 cases that had already been reported. Three views are held concerning the etiology: (1) the growths are due to embryonal rests; (2) they are due to failure of union between the glomeruli and the collecting tubules, and (3) they are retention cysts.

They are usually unilateral, the cyst being situated at one pole. The size of the cysts varies from about 30 cc. to 16 liters. In the majority of cases, the contents are described as clear serous fluid. Various complications are sometimes found, such as malignant disease, stones and tuberculosis. The average age of the patients is about 45. The cysts are somewhat more common in women.

Carson expressed the belief that polycystic kidney, solitary serous cyst of the kidney and solitary hemorrhagic cyst of the kidney are all the result of congenital malformations of the kidney and that a solitary hemorrhagic cyst is formed in the same way as a solitary serous cyst.

[ED. NOTE.—Solitary cysts occasionally present themselves as symptomless abdominal tumors. Prior to the period of pyelography, these cysts were not diagnosed before operation. At present, complete cystoscopic examination usually suggests the true diagnosis. The cyst may compress the renal pelvis either into an upper or lower position, or there is median or lateral displacement; the resulting deformity is outlined in a pyelogram. Usually there is no infection connected with the cysts, and at times at least two thirds of the kidney remains. These cysts can be resected readily, leaving a normally functioning kidney.

Echinococcus cysts are to be considered in all cases of large renal cysts. A number of such cases have recently been reported by Craig from Australia. In such cases, it is essential that the entire affected area be removed.]

Davis<sup>17</sup> stated that congenital polycystic kidneys are the most important deformities of the urinary system because of the extensive degree of involvement, the progressive character and the marked tendency to hemorrhage and infection. He reported a series of twenty-two cases.

The most conspicuous tissue changes in these kidneys are the incompleteness of development in the unit structures, the incomplete assembling, the cystic degeneration and the consequent pressure atrophy. The cysts are most common in the subcapsular zone at the line of fusion of the lobules. They occur in the capsular zone, cortex and medulla.

---

16. Carson, W. J.: Solitary Cysts of the Kidney, *Ann. Surg.* **87**:250, 1928.

17. Davis, J. E.: The Surgical Pathology of Malformations in the Kidneys and Ureters; a Study of Twenty-Two Cases of Bilateral Polycystic Kidneys, *J. Urol.* **20**:283, 1928.

Davis concluded from his study that congenital polycystic kidneys are caused by defective protoplasm, which may be inherited or congenital and is chiefly manifested by delayed differentiation. Growth impulse, differentiation and cystic degeneration are not identically timed in both kidneys or in different parts of the organs affected.

*Echinococcus Cysts*.—Craig and Brown<sup>18</sup> reported several cases of hydatid disease of the kidney; this disease is distributed throughout countries that have become famous for wool-growing, such as Australia, from which country these cases are reported.

In twenty-eight (1.9 per cent) of 1,468 patients with hydatid disease admitted to the Royal Prince Albert Hospital during the last forty-two years, the kidney was affected. Sixteen cases were reported in this article: eleven of the patients were males and five were females. The average age of the patients was 40 years; the youngest patient was 9 and the oldest, 67.

The hydatid embryo may reach the kidney at the primary infestation. Secondary infestation of the kidney may occur from rupture of a hydatid cyst into some part of the blood stream. So many tumors may be present clinically that a diagnosis of secondary malignant disease is made. This type of multiple foci is usually found only at necropsy.

The kidney is rarely invaded from a perirenal source. The hydatid embryo is blood-borne in the same way as a bacterial infarct and, like it, usually comes to rest in the outer part of the cortex of the kidney.

The situation of the embryo determines the course of the disease. Those in the upper pole are more fraught with danger than those in the lower, because of the proximity of the liver and spleen. In the lower pole, when the spherical hydatid reaches the capsule of the kidney, there is expansion downward, and an enormous growth may take place without interference with the important organs. Local peritonitis sometimes occurs as the growth expands, and in one case acute obstruction resulted from peritoneal adhesions. In the middle part of the kidney the parasite expands until eventually the whole organ is destroyed. Displacement of the kidney rarely occurs in this disease; it is the hydatid that becomes displaced.

Hydatids of the kidney may be divided into two natural groups, according to the symptoms and the treatment. In one group the hydatids communicate with the renal pelvis and in the other they do not. Those which communicate with the urinary channels have been classified as open and those which do not, as closed.

Until a hydatid has ruptured into a calix, the symptoms are those of renal tumor only. It is characteristic that the tumor may be large

---

18. Craig, Gordon, and Brown, R. K. L.: Hydatid Disease of the Kidney, Surg. Gynec. Obst. 46:668, 1928.

without disturbing the general health of the patient. When once the hydatid has burst into the urinary tract, the patient has symptoms of genito-urinary trouble. Hematuria, colic and the passage of daughter cysts either whole or collapsed are the three cardinal features of the history. The colic is similar to that caused by renal stone. Intervals between attacks vary from a few days to a few months, according to the relief of tension within the cyst.

Cystoscopic examination may reveal a turbid efflux from the ureter during an attack of hematuria. The mucous membrane of the bladder is rarely involved. Pyelography is of value when positive deformity is shown, but the absence of deformity does not exclude the presence of hydatid. In the diagnosis of the closed type of hydatid, the intradermal test of Casoni and the complement deviation test of Ghedini are of distinct value.

Nephrectomy is the operation of choice in cases of open hydatid. Marsupialization or nephrostomy after devitalization of the contents of cysts with solution of formaldehyde or alcohol is the safest and best operation for closed hydatid. Subtotal nephrectomy may prove a useful operation when the function of the other kidney is poor.

Operation was performed in thirteen of the sixteen cases in this series. There were no deaths due to operation.

Tapping as a therapeutic measure in such cases has become obsolete. The safest method to prevent escape of the contents of the cyst into the perirenal tissue is a two-stage operation. At the first step the cyst is exposed by the usual method and stitched to the abdominal wall. The wound through the abdominal muscles is left open and packed with gauze. From ten to fourteen days later, when adhesions have shut off the surrounding areas, the cyst is evacuated as described.

Farkas<sup>19</sup> stated that echinococcus infection of the kidney is rare. Israel did not find any in 2,000 operations on the kidney. Small vesicles and their contents are of diagnostic importance, as is eosinophilia. Usually the blood from the infected subject gives a strongly positive fixation reaction.

Farkas reported a case in which the patient had repeated attacks of renal colic. The urine contained many chitin-covered vesicles. A roentgenogram showed a calcified area in the liver. A left pyelogram showed some dilatation. The upper calix appeared to connect with a small cavity. Operation revealed a fluctuant cavity about 9 cm. in diameter in the upper pole of the kidney which contained many different sized vesicles. Treatment consisted of removal of the large cyst.

---

19. Farkas, Ignác: Entfernung eines Echinokokkus-Sackes aus einer Niere, Verhandl. d. deutsch. Gesselsch. f. Urol., 1927, p. 192; abstr., Ztschr. f. Urol. 24: 111, 1928.

*Stones.*—Braasch<sup>20</sup> stated that in forty-five of 133 cases in which operation for renal stone was performed it was found advisable to remove the kidney. This is due in part to the fact that in cases of renal stone the condition is not diagnosed and treated in the earlier stages. One way in which greater accuracy in diagnosis can be secured is to examine the urinary tract by the roentgen ray in every case of abdominal pain which is not typical of a special lesion in the abdomen. In certain cases, renal stones are present for a long time without causing pain. In other cases attacks occur only at long intervals, and the patient forgets his pain or neglects to have treatment. Sometimes an operation is advisable. In some cases the stone is quite small, less than 1 cm. in diameter, and it is questionable whether operation is justifiable. If a stone has been present less than six months and if it is so small that it can be passed spontaneously, it should be left alone. In cases in which the stone is too large to pass spontaneously and has been discovered accidentally, operation should be performed at once because complications will arise later.

Braasch is opposed to nonoperative treatment or conservative measures in surgical cases of renal stone. A common reason for nephrectomy is a previous unsuccessful operation on the kidney. Removal of stones from a kidney on which an operation has been performed previously is often unsatisfactory, and the kidney is usually so badly injured that nephrectomy is necessary.

There are apparently two factors in the etiology of the formation of renal stones—infection and disturbance in metabolism. Infection is probably more common and occurs secondary to a distant focus of infection.

Medical treatment will not destroy renal stones already formed, and it is questionable whether anything can be done to prevent the recurrence of stones, either by medication or cystoscopic manipulation.

Braasch stated that fluoroscopy at the time of the operation aids in insuring the removal of all stones from the kidney. If fluoroscopy is not available, as a substitute a film may be placed back of the kidney.

According to Beer,<sup>21</sup> the object of operation for renal stone is to remove all calculous material and at the same time to spare the kidney so that there will be little if any injury to the functional parenchyma.

Beer emphasized the importance of a careful preliminary urologic study to determine whether the kidney is infected, whether it is functioning sufficiently to be preserved and whether the opposite kidney is

20. Braasch, W. F.: *Calculi in the Urogenital Tract*, Wisconsin M. J. **27**:199, 1928.

21. Beer, Edwin: *Points in the Technic of Operative Removal of Kidney Stones*, Ann. Surg. **87**:428, 1928.

present and functioning in case nephrectomy should be necessary. For instance, if a kidney is infected and the stone is removed by nephrotomy, sutures passed through the kidney may lead to secondary diffuse infection and subsequent sacrifice of the kidney.

If the stone is in a solitary kidney, the kidney should be handled carefully and not dislocated from its normal position, the operation being done *in situ*. Beer reported the results from a study of 271 cases of calculi. The use of pyelotomy has been increased during the last few years in preference to nephrotomy.

Beer advocated the inverted S-shaped incision in the lumbar region as giving the best approach to the kidney for the removal of stone. After the kidney is exposed the ureter should be isolated and a double loop of catgut thrown loosely around this to prevent fragments slipping into the ureter. The combination of nephrotomy and pyelotomy is sometimes indicated. It is surprising how readily stones of the most remarkable and distorted shapes can be removed through a large pyelotomy incision. Beer also advocated washing out the renal pelvis with a strong stream of water introduced through a catheter.

The use of roentgenograms of the kidney made at the operating table and developed immediately, while the operation is in progress, is advocated. This is to supplement the use of the fluoroscope, as advocated by Brewer and Braasch. As advocated by Quinby, a film may be used, a needle being introduced into the kidney to indicate the upper or lower pole and to give the operator some idea of the relative distance of any overlooked stones from this marker.

If pyelotomy is impossible, Beer performs nephrotomy. A soft rubber tube may be clamped around the renal pedicle to give hemostasis. Roentgen control may also be used here. The open vessels of a nephrotomy wound on the cut surface can be tied readily by passing a suture on a fine needle armed with catgut around the exposed vessel twice and then tying it. In closing the nephrotomy wound, as few sutures as possible should be used, to avoid infecting or strangling the parenchyma. If the capsule is still adherent, mattress sutures of chromic catgut may be used close to the incision, a few sutures being taken well in from the convexity and a few more nearer the convexity. If, however, the capsule has been stripped back, no such support is present to prevent sutures from cutting into the parenchyma, and in such cases it is important to underpin sutures either with fat or muscle.

Whether the pyelotomy incision is accurately closed or not seems unimportant. As a rule, plain catgut sutures are placed in the pelvic wall to approximate the incision, especially if a wide pyelotomy has been made. Before the pelvis is closed, the double loop of catgut on the ureter should be removed after careful palpation of the ureter above the loop for possible fragments.

[ED. NOTE.—Beer's article is an outstanding contribution on surgical technic in the removal of renal stone. The use of roentgenograms as an adjunct to fluoroscopy at the operating table is an advance concerning which we may hear more in the light of clinical experience. When the fluoroscope was employed at the operating table by Braasch and Carman, it was at once recognized as an important aid in detecting and removing small stones or fragments of stone. Just how much greater the value will be of the actual film taken of the exposed kidney over the fluoroscope is a question which time will answer.

Beer's closure of nephrotomy wounds by the underpinning technic is well known and frequently applied by American urologists. Unquestionably the method is of value in avoiding undue constriction of areas of parenchyma which later may undergo necrosis, with destruction of function, hemorrhage or infection.]

In studying the influence of operative procedures on renal function in nephrolithiasis and nephroptosis, Smirnov<sup>22</sup> came to the following conclusions:

In the majority of cases following pyelotomy, the function is increased over that of kidneys not operated on. Ureterotomy definitely increases the function of both kidneys. Nephrotomy does not decrease the function of a diseased kidney; the decrease of function observed after operation usually returns to the normal at a later period. Nephrotomy with the removal of large stones sometimes affords diminished function of the kidney operated on. Nephropexy not only brings about relief from pain but sometimes augments the function of the kidney operated on.

*Infection.*—Čajka<sup>23</sup> reported a series of cases of renal infection during pregnancy. His material consisted of seventeen cases of pyelitis, one case of pyonephrosis, and eight cases of pyelonephritis in pregnant women from the third to the seventh month. In seven cases, the pregnancy was the first. In seven cases the colon bacillus was the infecting organism, and in two cases the staphylococcus was found. Three patients made good progress on conservative treatment, among them being a woman at full term with her only kidney infected. Abortion occurred in one patient. Five patients were operated on, among whom was one patient with right pyonephrosis, and double pelves and ureters. The upper ureter opened at the external urethral meatus. There were three patients on whom nephrotomy and decapsulation were performed;

22. Smirnov, N. A.: Der Einfluss der operativen Eingriffe auf die Nierenfunktion bei Nephrolithiasis und Nephroptosis, *Ztschr. f. urol. Chir.* **24**:143, 1928.

23. Čajka, A.: Zur Frage der Diagnose und Therapie der Pyelonephritiden der Schwangeren, *Verhandl. d. I. Kong. russ. Urol.* **31**:131, 1927; abstr., *Ztschr. f. urol. Chir.* **24**:124, 1928.

bilateral operations were performed on one patient. Among the cases reviewed in the literature were several anomalous conditions, such as the absence of one kidney and double kidneys.

In all cases the infection was in the right kidney; it was bilateral in several patients. The question of abortion or operation on the kidney is still unanswered, surgeons favoring abortion and gynecologists, operation.

Beckers <sup>24</sup> stated that little is known of the influence of pregnancy on nephritis. Persons with renal disease who must avoid any excess are endangered by pregnancy. The strain of gastro-intestinal and circulatory disturbances, as well as increased renal activity, generally falls on the poorly functioning kidney. Usually gastro-intestinal disturbances cause danger by permitting the absorption of toxic materials and the transfer of the colon bacillus from the bowel to the kidney through the circulation. The axiom that the pregnant woman must eat for two is decidedly to be avoided. The pressure of the pregnant uterus against the ureters is also a source of trouble. The possibility must be considered that an already existing disease might be made worse and that a chronic renal lesion may result from nephritis of pregnancy. In some cases the influence of the pregnancy is slight, but in most of the cases there is an increase in the intensity of the symptoms, which may even lead to hypertension and uremia. Chloride retention is rarely dangerous and seldom threatens the life of the fetus. In uric acid retention, the outlook for the life of the fetus is poor. For the mother, the dangerous period is during the puerperium. Pruritus, visionary disturbances and retinitis may be mentioned; the latter is especially prominent in primiparas. The children are usually born dead, and eclampsia threatens the mothers.

To end pregnancy, therapeutic abortion under ether anesthesia is recommended. During pregnancy, when salt retention occurs, rigid dietary restrictions must be carried out. Milk diets are eliminated in lieu of a varied diet without salt. In nitrogen retention, Beckers advised strong catharsis and regulation of diet consisting of butter, vegetables and fruits. In severe cases, abortion is recommended. In cases of hypertension, phlebotomy is used, with removal of about 500 cc. of blood.

Strauss <sup>25</sup> reviewed the results in nineteen patients with well controlled bacterial urinary infection treated with neoarsphenamine. All of the patients had chronic infection, often of several years' duration.

---

24. Beckers, René: Néphrites chroniques et gestation, *Rev. franç. de gynéc. et d'obst.* **22**:92, 1927; abstr., *Ztschr. f. urol. Chir.* **24**:115, 1928.

25. Strauss, Heinz: Neosalvarsan in der Behandlung von Harninfektionen, *Ztschr. f. Urol.* **21**:587, 1927; abstr., *Ztschr. f. urol. Chir.* **24**:83, 1928.

All known methods of treatment had been unsuccessful. Strauss attempted to bring out the definite indications in which the neoarsphenamine should be used. His observations led him to the conclusion that it is only successful in staphylococcic infections and that good results should not be expected in cases complicated by stone, prostatitis and spermocystitis as well as by the presence of an anaerobic infection or colon bacillus. In twenty-four of twenty-five cases following the initial injection of neoarsphenamine, the urine was changed from an alkaline to an acid condition.

Strauss does not subscribe to the widespread idea that benefits are to be derived from the formation of formaldehyde. Furthermore, he pointed out that the neoarsphenamine works in a double manner, as a disinfecting agent in the blood and tissues and by the formation of a germicidal substance in the urine. Injections of 0.15 Gm. of neoarsphenamine were given on three consecutive days.

Haslinger<sup>26</sup> stated that the contracted kidney which is the result of an acute inflammatory process in a kidney or which develops in the course of chronic renal infection is a distinct entity, different in causation, symptoms, pathologic change and treatment from the contracted kidney of nephritis. The process may involve both kidneys or only one. Infection limited to the kidney may in time affect the other kidney. The condition may develop as the result of a single or repeated infection, or as the result of a stone or of a chronic infectious process in the tonsils, teeth or genital organs. The histopathologic changes are characterized by the development of infectious, indurated, sclerotic lesions leading to shrinkage of the organ. Dilatation of the renal pelvis is fairly constant. Inflammatory perinephritic processes, as well as strictures of the urinary passages, are frequent forerunners of a pyelonephritic contracted kidney.

Among the symptoms are pain and fever, the latter especially in uremic states. Pus and bacteria in a catheterized specimen are significant. Functional insufficiency is common. Pyelography and ureterography aid in diagnosis.

Conservative treatment should always be attempted. This includes medical treatment, ureteral dilatations and pelvic lavage. Surgical procedures, in case of failure of conservative treatment to bring about improvement, consist of decapsulation, of freeing the kidney from pain-producing scars and of decapsulation combined with nephrotomy. Nephrectomy is indicated in only a few cases. In twenty cases observed by Haslinger in the Hochenegg Clinic, the colon bacillus alone was found in sixteen. In four other cases, bacteria other than the colon bacillus were present. Two patients were tuberculous. Four patients

---

26. Haslinger, K.: Die pyelonephritische Schrumpfnier, Ztschr. f. urol. Chir. 24:1, 1928.

had stones in the kidney; one patient had a stone in the ureter. Five patients had ureteral stenosis, ten had infection of the genital organs, and four had perinephritic inflammation.

*Hydronephrosis.*—Wolotzki<sup>27</sup> noted that there are several other causes of hydronephrosis besides stricture, some of the more common and significant being kinks and angulations of the ureter. Wolotzki called attention to several normal ureteral constrictions, such as occur at the ureteropelvic juncture, in the area in which the ureter crosses the iliac artery and, lastly, at the wall of the bladder. His conclusions are as follows:

Among the causes of hydronephrosis, angulation and kinking of the ureter are significant factors. The cause of these pathologic ureteral changes may be considered congenital disturbances and acquired dystopia due to loss of fat or trauma, which may also act in conjunction with the renal pedicle and aberrant vessels. Treatment is purely on an etiologic basis and consists of correcting the cause, usually through plastic surgery. If the case has advanced to a hydronephrotic sac, nephrectomy may be necessary, except in cases of single kidney in which the treatment is nephrostomy; these conditions should be found as early as possible so as to institute early treatment. The pyelogram is of great value in making an early diagnosis.

Flandrin<sup>28</sup> operated in two cases of hydronephrosis reported by Fey. One patient, aged 19, had had symptoms of hydronephrosis for six years. The pelvis had a capacity of 13 cc., and it did not contract normally. At operation a large vein was found crossing the anterior surface of the pouch. It was cut and ligated. The capacity of the pelvis was reduced to 9 cc.

The other patient was a woman, aged 65, who had suffered for thirty years with right renal colic. Hydronephrosis was diagnosed, and at operation an inferior polar artery was found passing in front of the ureter. The artery was left intact, but nephropexy was performed which gave complete relief.

*Renal Sympathectomy.*—Hess<sup>29</sup> stated that the operation of renal sympathectomy is feasible, easy and practicable. By its use many kidneys which otherwise would be sacrificed can now be saved. Before the application of renal sympathectomy in the human being, it was necessary to consider whether a condition would be caused which might destroy the function of the opposite normal kidney, or whether it was

---

27. Wolotzki, A.: Ueber die Harnleiterabbiegungen und Abknickungen und ihre Folgen für die Niere, *Ztschr. f. urol. Chir.* **24**:173, 1928.

28. Flandrin: Deux observations d'hydronéphrose par vaisseau anormal, *Presse méd.* **59**:936, 1928.

29. Hess, Elmer: Renal Sympathectomy, *J. Urol.* **20**:333, 1928.

necessary to denervate both kidneys so as to reestablish an equality of the burden. Both of these questions are answered in the negative.

Indications for the operation are as follows: nephralgia, unilateral hematuria, as an adjunct to the removal of stones in the pelvis of the kidney or ureter, anuria that lasts longer than a few hours, and possibly renal tuberculosis.

Hess carried out this operation in five cases. The technic is important: The kidney is exposed by any of the usual flank incisions. The perirenal fat is separated and the kidney delivered into the wound. The ureter is found and completely freed as far down in the pelvis as possible. An attempt is not made to conserve the blood supply, the nerve supply or the lymphatics in this freeing. The little vessels running into the parenchyma of the kidney, through the capsule, are sacrificed in the delivery. Retractors are placed in the wound so that the exposure of the pedicle is facilitated, and with gauze the pedicle is gently stripped of all of its fatty sheath, care being taken not to injure the thin-walled veins. This fatty sheath containing lymphatics and nerves is stripped as far down toward the aorta and vena cava as possible. The fibrous sheath surrounding the arteries and veins is gently teased away with forceps and stripped back away from the kidney. Small nerve filaments or lymphatics are picked up on a grooved director and cut until the vessels of the pedicle are left completely exposed on all sides from any fascial covering for a distance of at least 1.5 cm. and preferably farther.

Hess' five patients were relieved of their clinical symptoms. Kidneys which ordinarily would have been removed have been saved. Three patients were operated on more than a year before the paper was written and were free from their previous clinical symptoms. The amount of urine secreted by the sympathectomized kidney after six months is about one-fifth more than that of the opposite kidney. Hess had never denervated both kidneys.

Nothing has been developed to show that the operation has any influence on the opposite or normal kidney. Pyelography prior to operation caused nausea and in two cases vomiting, although small amounts of sodium iodide were used. After operation this syndrome was not noted in any of these cases at the time of pyelography. Difficulty had not been encountered in passing ureteral catheters after operation, and there seemed not to have been any evidence of kinking or stricture of the ureters such as is obtained in some of the cases prior to operation.

*Lymphatic Drainage.*—Syzganov<sup>30</sup> based his study of the lymphatic system of the kidney on the examination of the bodies of seventy-five

30. Syzganov, A.: Ueber das lymphatische System der menschlichen Niere, Verhändl. d. I. Kong. russ. urol. **31**:33, 1927; abstr., Ztschr. f. urol. Chir. **24**:4, 1928.

children. He employed red and blue injection masses, using Herot's technic. The right kidney possessed several efferent systems, which Syzganov divided into three groups: (1) the lymphatics of the superficial surface and also partly of the deeper and middle layers; the lymph nodes between the aorta and the inferior vena cava from the level of the left renal vein down to the bifurcation of the aorta; (2) the lymphatics of the middle layer and part of the superficial and deep layers; the lymph nodes of the spaces mentioned which lie in a deeper region, and the lymph nodes behind the right renal vein, and (3) the lymphatics of the deeper layer and the lymph nodes behind the renal artery.

The vasa efferentia of the lymph nodes of the spaces between the vessels end in glands which are in connection with the right and left lumbar ductus; some end directly in the thoracic duct. The left kidney possesses a greater number of efferent vessels, grouped as follows: (1) most of the superficial lymphatic vessels and part of the deep and middle sinuses; the lymph nodes which lie superficially on the left border of the aorta and beneath the left renal vein; (2) the middle and part of the superficial and deep vessels; the lymph nodes which lie anteriorly at the level of the left renal artery, and (3) vessels of all three layers; the lymph nodes lying along the left border of the aorta.

The vasa efferentia of these nodes help to form the left lumbar ductus, and some enter directly into the thoracic duct. The structure of the lymph channels of both kidneys is asymmetrical on account of the variation of the origin of both kidneys from the cisterna chyli and the beginning of the thoracic duct; also, there is a variation in the communication of the proximal channels with the neighboring organs.

The lymphatics of the right suprarenal gland, together with those of the right testicle, the undersurface of the right lobe of the liver, the undersurface of the right half of the diaphragm, the ascending colon, the cecum and the appendix empty into the lymph nodes of the right kidney. Into the lymph nodes of the left kidney empty the channels of the left suprarenal gland, the left testicle, the pancreas, the upper surface of the right lobe of the liver and the under surface of both halves of the diaphragm. Aside from these, there are connections between the lymphatics of both kidneys and the gastro-intestinal tract. In some cases the superficial lymphatic system of the intestine, ascending colon, cecum and appendix communicates directly with the right kidney. The lymphatics of the renal capsule are as side branches and communicate with the nodes lying between the aorta and inferior vena cava. Less frequently, the lymph channels of the anterior surface of the kidney communicate with the glands at the ileocecal juncture.

Injections of the lymph channels of the fibrous capsule were unsuccessful.

*Hematoma.*—Heilmann<sup>31</sup> removed a right kidney from an acutely ill man, aged 64. The kidney contained a large hematoma involving the entire fatty capsule. It arose from the surface of the kidney and was separated from it by a thin fibrotic layer. The parenchyma was macroscopically and microscopically normal. Small thin-walled vessels led from the margin of the kidney into the hematoma itself. These vessels were surrounded by a circle of polymorphonuclear leukocytes. An increase of the capillaries, hyperplasia of the endothelium or rupture of any larger vessels did not occur.

Heilmann considered the hematoma a massive capillary hemorrhage in the connective tissue and fatty capsule of the kidney. He accepted the theory of Rickers that this type of hematoma can be explained by vasomotor destruction and resulting diapedesis. He recalled similar hemorrhages in pancreatic apoplexy, idiopathic renal bleeding, a type of cerebral hemorrhage and internal hemorrhagic pachymeningitis.

*Essential Hematuria.*—According to Rømcke and Trygve,<sup>32</sup> there are cases of essential hematuria in which neither pathologic nor anatomic evidence is to be found, but such cases are gradually decreasing as diagnostic measures become more efficient. The diagnosis of essential hematuria should be made only as a last resort. The many causes of hematuria discussed in the literature should all be carefully considered. The authors discussed seventeen cases of their own which clinically were essential hematuria. Operation was performed in all cases and, with two exceptions, histologic examinations were made. The clinical symptoms consisted usually only of hematuria for a varying length of time (from several days to twenty years) and of varying intensity. Deficient renal function was not shown in any case. Hemophilia and hysteria were ruled out in all cases. Nephrectomy was performed in ten cases and in seven, nephrotomy and decapsulation. In one of the latter cases secondary nephrectomy was done. Seven patients were well after nephrectomy. One patient with continued hematuria had carcinoma of the prostate, and the results with regard to two patients were not ascertained. Following nephrotomy five recovered; one died following secondary nephrectomy, and the condition of one remained unchanged.

Histologic examination of specimens from fifteen cases revealed microscopic nephritic changes in five cases, the changes of pyelonephritis in one case and subcapsular bleeding in one; a definite change was not noted in eight cases. The nephritic changes consisted of interstitial round-cell infiltration. Definite glomerular changes were found in only

32. Rømcke, Olaf; and Trygve, Serck-Hanssen: Essentielle Nierenblutung, Acta chir. Scandinav. **62**:211, 1927.

one case. Rømcke expressed the belief that in the cases in which lesions were not demonstrable the pathologic process lay in another plane or was focal.

*Suprarenal-Renal Heterotopia.*—Caylor<sup>33</sup> reported a case of suprarenal-renal heterotopia (developmental inclusion of the suprarenal gland beneath the capsule of the kidney). The kidney was removed because of hydronephrosis. The anterosuperior surface of the kidney was covered by a yellow area, which was found to be the suprarenal gland. After the capsule was stripped from the kidney, the gland was found beneath it.

About thirteen cases of this condition have been reported in the literature. It is of surgical importance because with the removal of the kidney the removal of the suprarenal gland also might have an adverse result by reducing the potential production of epinephrine. Since the medullary substance is diminished, injections of epinephrine postoperatively may combat the evident insufficiency. In the case reviewed, it was impossible to save the suprarenal gland because it was wholly beneath the capsule of the kidney.

(To be Continued)

This issue of the ARCHIVES OF SURGERY is a special number in honor of the sixtieth birthday of Dr. Harvey Cushing. All of the authors are former pupils of Dr. Cushing, and have contributed toward the publication.

THE EDITORS.

Harvey Cushing

## HARVEY CUSHING

Born in Cleveland, Ohio, April 8, 1869. Brother of Edward F. Cushing (1862-1911), M.D. (Harvard), late Professor of Pediatrics, Western Reserve Medical School; son of Henry K. Cushing (1827-1910), M.D. (Univ. of Penn.), LL.D., formerly Professor of Obstetrics and Gynaecology, Western Reserve Medical School; grandson of Erastus Cushing (1802-1893), M.D. (Berkshire Medical School); great grandson of Dr. David Cushing, Jr. (1768-1814) of Cheshire, Massachusetts.

---

Bachelor of Arts, Yale, 1891.

Doctor of Medicine, Harvard; Master of Arts (*ibid.*), 1895.

House Officer, Massachusetts General Hospital, 1895-1896.

Johns Hopkins Hospital and Medical School, 1896-1900.

Assistant Resident Surgeon, October, 1896-October, 1897.

Resident Surgeon, October, 1897-May, 1900.

Instructor in Surgery, 1897-1898.

Assistant in Surgery, 1898-1899.

Associate in Surgery, 1899-1903.

American Association of Pathologists and Bacteriologists, 1900.

Student under Theodore Kocher and Hugo Kronecker (Bern) and Charles S. Sherrington (Liverpool), 1900-1901.

Johns Hopkins Hospital and Medical School, 1901-1912.

Associate in Surgery, March, 1902-September, 1912.

Associate Professor of Surgery, 1903-1912.

Mütter Lecturer (Philadelphia), 1901.

American Neurological Association, 1903 (President, 1923).

Charter member, American Society of Clinical Surgery, 1903 (President, 1921).

Member, American Physiological Society, 1905.

Fellow, American Surgical Association, 1906 (President, 1927).

Wesley M. Carpenter Lecturer (New York), 1906.

William Mitchell Banks Memorial Lecturer (University of Liverpool), 1909.

Member, Royal Medical Society of Budapest, 1909.

Harvey Lecturer (New York), 1910.

Appointed Moseley Professor of Surgery, Harvard University, 1911.  
(Incumbent, 1912—).

Surgeon-in-Chief, Peter Bent Brigham Hospital, 1912—.

Master of Arts, Yale, 1913.

Oration in Surgery, XVIIth International Congress of Medicine (London), 1913.

Fellow of the Royal College of Surgeons, England, 1913.

Fellow of the Institute of Hygiene (London), 1913.

Fellow of the American College of Surgeons, 1913 (President, 1922).

Weir Mitchell Lecturer (Philadelphia), 1914.

Foreign member, Société de Neurologie, Paris, 1914.

American Academy of Arts and Sciences, 1914.

Washington Academy of Sciences, 1914.

National Academy of Sciences, 1917.

Fellow, Societas Medicorum Svecana, 1917.

Director, U. S. Army Base Hospital No. 5, 1916-1919.

Senior Consultant in Neurological Surgery, A. E. F., 1918.

Fellow, Royal College of Surgeons (Ireland), 1918.

Doctor of Science, Washington University, 1919.

Doctor of Laws, Western Reserve University, 1919.

Doctor of Science, Yale, 1919.

Companion of the Bath (Military), 1919.

Doctor of Medicine, Queen's University, Belfast, 1919.

Membre associé Société Royale de Sciences Médicales et Naturelles de Bruxelles, 1919.

Charter member, Society of Neurological Surgeons, 1920 (President, 1920 and 1921).

Doctor of Laws, Cambridge, 1920.

Corresponding member, Société de Biologie, Paris, 1920.

Honorary Fellow of the Medical Society of London, 1921 (Orator, 1927).

Corresponding member, Gesellschaft der Aerzte, Wien, 1921.

Charles Mickle Fellow, University of Toronto, 1922.

Cavendish Lecturer (London), 1922.

Perpetual Student (*honorary*), St. Bartholomew's Hospital (London), 1922.

## TABLE OF CONTENTS

---

The contributors to this volume consider themselves pupils of Professor Harvey Cushing in the sense that from their period of affiliation with him they derived stimulation and inspiration of such quality as to influence largely their future careers.

Their contributions in this birthday book are arranged chronologically according to the time of their association with their "Chief."

GEORGE J. HEUER, B.Sc., M.D.

*Assistant Resident Surgeon, Johns Hopkins Hospital, 1908-1909.*

*Professor of Surgery, University of Cincinnati College of Medicine; Surgical Director, Cincinnati General Hospital.*

The So-Called Hour-Glass Tumors of the Spine..... 935

S. J. CROWE, A.B., M.D.

*Assistant in Surgery, Hunterian Laboratory, Johns Hopkins Medical School, 1908-1909; Assistant Resident Surgeon, Johns Hopkins Hospital, 1909-1910. Clinical Professor of Otology and Laryngology, Johns Hopkins University; Otolaryngologist to the Johns Hopkins Hospital.*

Anatomic Changes in the Labyrinth Secondary to Cerebellopontile and Brain Stem Tumors..... 982

JOHN HOMANS, A.B., M.D.

*Assistant in Surgery, Hunterian Laboratory, Johns Hopkins Medical School, 1908-1909; Surgeon, Peter Bent Brigham Hospital, May 1, 1912. Instructor in Surgery, Harvard Medical School; Surgeon, Peter Bent Brigham Hospital.*

Experimental Thrombophlebitis and Lymphatic Obstruction of the Lower Limb: A Preliminary Report..... 992

EMIL GOETSCH, S.B., Ph.D., M.D.

*Assistant in Surgery, Hunterian Laboratory, Johns Hopkins Medical School, 1909-1910; Assistant Resident Surgeon, Johns Hopkins Hospital, 1910-1912; Resident Surgeon, Peter Bent Brigham Hospital, Sept. 1, 1912-Sept. 1, 1915. Professor of Surgery, Long Island College Hospital; Surgeon in Chief, Long Island College Hospital.*

The Diagnosis and Surgical Treatment of Carcinoma of the Colon..... 998

CLIFFORD B. WALKER, B.S., M.D.

*Assistant to Dr. Cushing, Johns Hopkins Hospital, 1911-1912; Associate in Surgery, Peter Bent Brigham Hospital, March 1, 1915-April 25, 1918. Member of the Attending Staff of the Eye Service of the Los Angeles General Hospital; Member of the Attending Staff of the Eye Service of the Good Samaritan Hospital; Member of the Attending Staff of the Eye Service of the California Lutheran Hospital, Los Angeles, Calif.*

The Time Element in Quantitative Perimetry..... 1036

LEWIS H. WEED, A.B., M.D.

*Surgeon, Peter Bent Brigham Hospital, Oct. 1, 1912—. Associate Professor of Surgery, Harvard Medical School; Surgeon to the Peter Bent Brigham Hospital, Boston.*

Instrumental Dilatation of the Papilla of Vater and the Dislodgment of Calculi by Retrograde Irrigation: A Contribution to the Surgery of the Bile Passages..... 1069

CHARLES BAGLEY, JR., A.B., M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Jan. 1, 1913-Jan. 1, 1914. Associate in Experimental Neurology, Johns Hopkins Medical School; Visiting Surgeon, Sinai Hospital Church Home and Infirmary, St. Agnes Hospital, Bon Secours Hospital, West Baltimore General Hospital, Maryland General Hospital, Union Memorial Hospital, Provident Hospital and Free Dispensary, Baltimore; Consulting Surgeon, Baltimore Eye, Ear and Throat Charity Hospital, Emergency Hospital, Annapolis, Md., Presbyterian Eye, Ear and Throat Charity Hospital, St. Joseph's Hospital, South Baltimore General Hospital, Baltimore, Alleghany Hospital, Cumberland, Md., and Waynesboro Hospital, Waynesboro, Pa.; Assistant Psychiatrist, Johns Hopkins Hospital.*

The Grouping and Treatment of Acute Cerebral Traumas..... 1078

ARTHUR GOETSCH, S.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, 1913. Associate Professor of Surgery, Long Island College Hospital; Attending Surgeon, Long Island College Hospital; Chief, Surgical Clinic No. 3, Long Island College Hospital.*

The Diagnosis and Surgical Treatment of Carcinoma of the Colon..... 998

JOHN J. MORTON, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1913-July 1, 1914. Professor of Surgery, University of Rochester School of Medicine and Dentistry, Rochester, N. Y.; Surgeon-in-Chief, Strong Memorial and Rochester Municipal Hospitals.*

The Differences Between High and Low Intestinal Obstruction in the Dog: An Anatomic and Physiologic Explanation..... 1119

GILBERT HORRAX, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1913-Nov. 1, 1914; Arthur Tracy Cabot Fellow, 1914-1915; Assistant Resident Surgeon, Peter Bent Brigham Hospital, 1915-1916; Associate in Neurological Surgery, Peter Bent Brigham Hospital, October, 1919-March, 1928; Senior Associate in Neurological Surgery, Peter Bent Brigham Hospital, March, 1928—. Instructor in Surgery and Secretary*

of the Department, Harvard Medical School; Senior Associate in Neurological Surgery, Peter Bent Brigham Hospital; Neurological Surgeon, Children's Hospital, Boston; Consultant in Neurological Surgery in the N. E. Deaconess Hospital, Boston, and to the Sturdy Memorial Hospital, Attleboro, Mass.

Experiences with Cordotomy..... 1140

E. B. TOWNE, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1913-Nov. 1, 1914; Assistant Resident Surgeon, Peter Bent Brigham Hospital, Nov. 1, 1914-Nov. 1, 1915, and Sept. 1, 1916-May 7, 1917. Associate Clinical Professor of Surgery, Stanford University Medical School; Visiting Surgeon to the City and County Hospital of San Francisco, and the Southern Pacific General Hospital of San Francisco.*

Experimental Diabetes Insipidus..... 1165

CARL WHEELER RAND, A.B., A.M., M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Oct. 1, 1913-Nov. 1, 1914. Senior Attending Physician on the Brain and Neurological Service at the Los Angeles County General Hospital; Member of the Staffs of Children's Hospital, Good Samaritan Hospital, California Lutheran Hospital, Santa Fe Hospital and Hollywood-Clara Barton Hospital, Los Angeles.*

The Significance of a Dilated Pupil on the Homolateral Hemiplegic Side in Cases of Intracranial Hemorrhage Following Head Injuries: Report of Seven Cases..... 1176

ELLIOTT C. CUTLER, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1913-March 1, 1915; Resident Surgeon, ibid., Aug. 1, 1919-Sept. 1, 1921; Associate in Surgery, ibid., Sept. 1, 1921-July 1, 1924. Professor of Surgery, Western Reserve University School of Medicine; Director of Surgery, Lakeside Hospital, Cleveland.*

The Art of Surgery..... 1190

STANLEY COBB, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1914-July 1, 1915. Bullard Professor of Neuropathology, Harvard Medical School; Visiting Physician for Neurology, Boston City Hospital.*

The Cerebral Circulation: VIII. A Quantitative Study of the Capillaries in the Hippocampus..... 1200

EDWIN P. LEHMAN, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1914-July 1, 1915. Professor of Surgery and Gynecology, and Director of the Surgical Service, University of Virginia.*

A Note on the Academic Life..... 1210

M. N. SMITH-PETERSEN, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1914-Nov. 1, 1915. Instructor of Orthopedic Surgery, Harvard Medical*

School; Assistant Orthopedic Surgeon, Massachusetts General Hospital.	
Traumatic Arthritis: Histologic Changes in Hyaline Cartilage.....	1216
SAMUEL C. HARVEY, PH.B., M.D.	
<i>Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1914-Nov. 1, 1915; Arthur Tracy Cabot Fellow, 1915-1916; Assistant Resident Surgeon, Peter Bent Brigham Hospital, Nov. 1, 1916-May 7, 1917. Professor of Surgery, Yale University School of Medicine; Surgeon-in-Chief, New Haven Hospital; Chief of Service, Surgical Clinic, New Haven Dispensary.</i>	
The Velocity of the Growth of Fibroblasts in the Healing Wound.....	1227
JAMES C. JANNEY, A.B., M.D.	
<i>Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1915-Nov. 1, 1916. Instructor in Gynecology and Obstetrics, Boston University School of Medicine; Second Assistant Obstetrician, and Gynecologist to Out-Patient Department, Massachusetts Homeopathic Hospital; Obstetrician to Florence Crittenton Hospital, Boston.</i>	
Ovarian Follicular Hormone: A Preliminary Communication.....	1241
HARRIS H. VAIL, A.B., M.D.	
<i>Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1916-May 3, 1917; Voluntary Graduate Assistant, ibid., Jan. 5, 1920-April 10, 1920. Instructor in Otolaryngology, University of Cincinnati College of Medicine; Attending Laryngologist, Cincinnati General Hospital; Clinician Out-Patient Department of Otolaryngology, Cincinnati General Hospital; Attending Otolaryngologist, Tuberculosis Service, Cincinnati General Hospital; Assistant Attending Laryngologist at the Episcopal Hospital for Children, Cincinnati, Ohio.</i>	
Vidian Neuralgia from Disease of the Sphenoidal Sinus: Report of a Case	1247
WILLIAM C. QUINBY, A.B., M.D.	
<i>Urological Surgeon, Peter Bent Brigham Hospital, June 19, 1916—. Clinical Professor of Genito-Urinary Surgery, Harvard Medical School; Urologist, Peter Bent Brigham Hospital.</i>	
The Teaching of Urology in the Surgical Curriculum.....	1256
LOUIS F. FALLON, M.D.	
<i>Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1916-Nov. 15, 1916. Attending Surgeon, St. Clare's Mercy Hospital and Sudbury Children's Hospital, St. John's, Newfoundland.</i>	
Cholecystotomy Versus Cholecystectomy.....	1259
VINCENT J. O'CONOR, B.S., M.D.	
<i>Surgical House Officer, Peter Bent Brigham Hospital, Jan. 1, 1917-Jan. 1, 1918; Assistant Resident Surgeon, ibid., Feb. 15, 1919-July 15, 1920. Assistant Professor of Surgery (Genito-Urinary), University of Illinois College of Medicine; Urological Surgeon to the Washington Boulevard, Garfield Park and Lutheran-Deaconess Hospitals of Chicago.</i>	
Nephrolysis, Ureterolysis and Nephropexy: An Analysis of Thirty Consecutive Operations with Description of Technic.....	1263

HENRY R. VIETS, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1917-Aug. 16, 1917.* Instructor in Neurology, Harvard Medical School; Assistant Neurologist, Massachusetts General Hospital; Consulting Neurologist, Massachusetts Eye and Ear Infirmary.

"De l'Auscultation Médiate" of Laennec..... 1280

ARCHIE L. DEAN, JR., B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, May, 1917-February, 1918.* Associate Attending Surgeon, Memorial Hospital; Associate Attending Urologist, Fifth Avenue Hospital; Visiting Urologist, Reconstruction Hospital; Consulting Urologist, Somerset Hospital, New York.

Epithelioma of the Penis: Treatment with Radium and the Roentgen Rays 1273

RAMSAY SPILLMAN, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1917-March 1, 1918.* Roentgenologist, Beekman Street Hospital, New York.

Dermoid Cysts of the Ovary: Roentgen Observations..... 1298

WILLIAM EDWIN GABE, M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1918-March 31, 1919.* Surgical Staff, Methodist Episcopal Hospital; Visiting Staff in Gynecology, Indianapolis City Hospital; Associate Staff, St. Vincent's Hospital, Indianapolis.

Torsion of the Undiseased Fallopian Tube..... 1304

ERIC STONE, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, May 15, 1918-July 1, 1919; Assistant Resident Surgeon, ibid., Oct. 1, 1919-June 15, 1920.* Surgeon-in-Charge, Urological Service, Providence City Hospital; Urological Consultant, Providence Lying-In Hospital; Surgeon, Urological Service, Memorial Hospital, Pawtucket; Assistant Surgeon, Gynecological Service, Rhode Island Hospital.

Lesions of the Posterior Urethra in Chronic Gonorrhea: Cysto-Urethroscopic Observations ..... 1315

STEELE F. STEWART, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, June 1, 1918-July 1, 1919.* Associate Orthopedic Surgeon, Children's Hospital, Los Angeles.

Dysphasias of Cortical Rigidity and Their Treatment: A Preliminary Report ..... 1329

WILDER PENFIELD, Litt.B.; B.A., M.A., B.Sc. (Oxford); M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Aug. 15, 1918-Sept. 20, 1919.* Clinical Professor of Neurological Surgery, McGill University, Montreal; Surgeon in Charge of Neurological Surgery at the Royal Victoria and Montreal General Hospitals.

The Scope of Neurology..... 1335

FRANCIS C. NEWTON, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 15, 1919-July 1, 1920; Assistant Resident Surgeon, ibid., July 1, 1920-Sept. 1, 1921; Resident Surgeon, ibid., Sept. 1, 1921-July 1, 1923; Junior Associate in Surgery, ibid., July 1, 1923-Sept. 15, 1923; Associate in Surgery, ibid., June 15, 1924-March, 1928; Senior Associate in Surgery, ibid., March 8, 1928—.* Faculty Instructor in Surgery, Harvard Medical School; Senior Associate in Surgery, Harvard Medical School; Supervisor of Laboratory of Surgical Research, Harvard Medical School; Senior Associate in Surgery, Peter Bent Brigham Hospital.

Acquired Diverticula of the Colon: A Study of the End-Results in Forty-Four Cases ..... 1339

PERCIVAL BAILEY, B.S., PH.D., M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, April 1, 1919-Dec. 19, 1919; Arthur Tracy Cabot Fellow, 1920-1921 and Associate in Surgery, Peter Bent Brigham Hospital, Sept. 1, 1920-July 1, 1921; Junior Associate in Surgery, ibid., July 1922-Sept., 1923; Associate in Surgery, ibid., Sept. 14, 1923-July 1, 1928.* Associate Professor of Surgery, University of Chicago; Surgeon to the Albert Merritt Billings Hospital; Consulting Neurological Surgeon to the St. Luke's Hospital, Chicago.

Intracranial Sarcomatous Tumors of Leptomeningeal Origin..... 1359

GEORGE B. WISLOCKI, A.B., M.D.

*Arthur Tracy Cabot Fellow, 1919-1920 and Associate in Surgery, Peter Bent Brigham Hospital, March 25, 1920-Oct. 1, 1920.* Associate Professor of Anatomy, Johns Hopkins University.

The Hypophysis of the Porpoise (*Tursiops Truncatus*)..... 1403

FREDERIC E. B. FOLEY, PH.B., M.D.

*Assistant in Laboratory of Surgical Research, Harvard Medical School, 1919-1920; Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1920-July 1, 1921.* Instructor in Urology, University of Minnesota Medical School; Chief Urologist, Ancker Hospital, St. Paul; Visiting Urologist, Charles T. Miller Hospital, St. Paul.

Improved Methods for Nephropexy and for Exposure of the Kidney..... 1413

A. H. BREWSTER, B.A., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Feb. 15, 1920-July 1, 1921.* Instructor in Orthopedic Surgery, Harvard Medical School; Visiting Surgeon, New England Peabody Home for Crippled Children; Visiting Surgeon, Industrial School for Crippled Children, Boston; Assistant Surgeon, Children's Hospital, Boston.

Lateral Structural Curvature of the Spine: Treatment by Means of the Turnbuckle Jacket and Turnbuckle Shell..... 1427

CHARLES EDWARD LOCKE, JR., A.B., M.S., M.D.; S.D. (Brussels).

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, June 15, 1920-June 1, 1921.* Neurological Surgeon, Cleveland Clinic Founda-

tion; Consulting Neurological Surgeon, Charity Hospital, Glenville Hospital, Woman's Hospital and Lutheran Hospital, Cleveland.

Increased Intracranial Pressure Associated with Syphilis..... 1446

FRÉDÉRIC BREMER, Docteur en Médecine de l'Université de Bruxelles.

*Voluntary Graduate Assistant, Peter Bent Brigham Hospital, Oct. 1, 1920-May, 1921. Agrégé de Physiologie de l'Université de Bruxelles.*

The Tonus and Contracture of Skeletal Muscles..... 1463

MAXWELL HARBIN, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1920-March 1, 1921. Assistant Professor of Orthopedic Surgery, Western Reserve University School of Medicine; Associate Orthopedic Surgeon, Lakeside Hospital; Surgeon-in-Charge, Rainbow Hospital.*

Deposition of Calcium Salts in the Tendon of the Supraspinatus Muscle.. 1491

D. C. ELKIN, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1921-July 1, 1922; Assistant Resident Surgeon, ibid., July 1, 1922-July 1, 1923; Resident Surgeon, ibid., July 1, 1923-Sept. 1, 1923. Associate in Surgery, Emory University; Surgeon-in-Chief, Henrietta Eggleston Hospital for Children; Surgeon to Steiner Clinic; Assistant Visiting Surgeon to Grady Hospital; Assistant Visiting Surgeon to Wesley Memorial Hospital.*

Primary Neoplasms of the Lymph Nodes: A Clinical Study of Forty-One Cases ..... 1513

PAUL MARTIN, B.S., M.D. (Brussels).

*Associate in Surgery, Peter Bent Brigham Hospital, Sept. 1, 1921-March 1, 1922; Assistant Resident Surgeon, ibid., March 1, 1922-November, 1922. Assistant au 1er Service Universitaire de Chirurgie, Bruxelles.*

Tumors of the Brain and Syphilis..... 1531

HARLAN F. NEWTON, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1921-March 1, 1923; Assistant Resident Surgeon, ibid., Oct. 1, 1923-July 1, 1924; Resident Surgeon, ibid., July 1, 1924-Oct. 1, 1926; Junior Associate in Surgery, ibid., Oct. 1, 1928—. Austin Teaching Fellow in Surgery, Harvard Medical School; Junior Associate in Surgery, Peter Bent Brigham Hospital.*

The Effect of Ultraviolet Light on Corneal Tuberculosis in Rabbits..... 1542

WILLIAM C. WARREN, JR., B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 28, 1922-July, 1923. Assistant Otolaryngologist at Emory University; Visiting Otolaryngologist at Wesley Memorial Hospital, Atlanta.*

Intracranial Complications in Purulent Otitis Media..... 1552

JEROME R. HEAD, A.M., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1922-Nov. 1, 1923. Instructor in Surgery in the Medical School of the*

University of Illinois, Chicago; Attending Surgeon of the Research and Educational Hospital of the University of Illinois and the Grant Hospital, Chicago.

John Brown on Medical Education..... 1562

JAMES J. JOELSON, M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, July 15, 1922-July 26, 1923. Assistant Professor of Genito-Urinary Surgery, Western Reserve University School of Medicine; Associate Genito-Urinary Surgeon, Lakeside Hospital, Cleveland.*

Pyelitis, Ureteritis and Cystitis Cystica: Report of a Case Showing Urographic Evidence of the Lesion in the Ureters and Pelves..... 1570

W. J. MERLE SCOTT, A.B., A.M., M.D.

*Arthur Tracy Cabot Fellow, 1922-1923 and Associate in Surgery, Peter Bent Brigham Hospital, Sept. 1, 1922-July 1, 1923; Assistant Resident Surgeon, ibid., July 1, 1923-July 1, 1924. Associate Professor of Surgery, University of Rochester School of Medicine and Dentistry, Rochester, N. Y.; Associate Surgeon, Strong Memorial Hospital and Rochester Municipal Hospital.*

The Relationship of Nonabsorbable Suture Material to Jejunal Ulcer: An Experimental Study..... 1584

KENNETH G. MCKENZIE, M.B., M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Nov. 1, 1922-Nov. 1, 1923. Junior Demonstrator in Surgery and Clinical Surgery, Assistant in Neurology, University of Toronto; Junior Assistant Surgeon, Division 1, Toronto General Hospital.*

The Treatment of Abscess of the Brain..... 1594

WILLIAM P. VAN WAGENEN, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1922-March 1, 1924; Assistant Resident Surgeon, ibid., Oct. 1, 1924-Nov. 1, 1925. Instructor in Surgery, University of Rochester School of Medicine and Dentistry, Rochester, N. Y.; Assistant Surgeon, Neurological Surgery, Strong Memorial Hospital.*

Elastic Tissue in Meningeal Fibroblastomas; So-Called "Dural Endotheliomas" ..... 1621

DOUGLAS BOYD, M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1923-July 1, 1924; Assistant Resident Surgeon, July 1, 1924-Aug. 1, 1924. Practice, Traumatic Surgery, Chicago.*

Post-Traumatic Headache Treated by Spinal Insufflation of Air..... 1626

J. PATERSON ROSS, M.B. (London)

*Junior Associate in Surgery, Peter Bent Brigham Hospital, April 9, 1923-Sept. 14, 1923. First Assistant in the Surgical Professorial Unit, St. Bartholomew's Hospital, London.*

Notes on the Barbers' Hall in London..... 1637

# TABLE OF CONTENTS

xvii

CLARENCE E. BIRD, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1923-Nov. 1, 1924; Assistant Resident Surgeon, ibid., July 1, 1925-Oct. 1, 1926; Resident Surgeon, ibid., Oct. 1, 1926-Sept., 1928.*

Transfusions in Acute Loss of Blood..... 1646

CLAUDE S. BECK, A.B., M.D.

*Arthur Tracy Cabot Fellow, 1923-1924 and Associate in Surgery, Peter Bent Brigham Hospital, 1923-1924; Assistant Resident Surgeon, ibid., April 9, 1927-June, 1927. Assistant Professor of Surgery, Western Reserve University School of Medicine; Associate Surgeon, Lakeside Hospital, Cleveland.*

The Effect of Surgical Solution of Chlorinated Soda (Dakin's Solution) in the Pericardial Cavity..... 1659

EMILE HOLMAN, A.B., B.A. (Oxon.), M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, July 15, 1923-Sept. 1, 1923; Resident Surgeon, ibid., Sept. 1, 1923-July 1, 1924. Professor of Surgery, Stanford University Medical School; Surgeon, Stanford University Hospital, San Francisco.*

Arteriovenous Fistula: Dilatation of the Artery Distal to the Abnormal Communication; An Unusual Feature Experimentally Explained.... 1672

LOYAL DAVIS, M.D., M.S., Ph.D.

*Voluntary Graduate Assistant, Peter Bent Brigham Hospital, September, 1923-March, 1924; Junior Associate in Surgery, ibid., March, 1924-October, 1924. Associate Professor of Surgery, Northwestern University Medical School; Attending Neurologic Surgeon, Wesley Memorial Hospital, Chicago.*

Muscle Tone in Decerebrate Rigidity..... 1687

TRACY J. PUTNAM, A.B., M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Nov. 1, 1923-Oct. 1, 1924; Arthur Tracy Cabot Fellow, 1925-1926; Associate in Surgery, Peter Bent Brigham Hospital, Aug. 1, 1925-Sept. 15, 1928. Assistant in Surgery and Research Fellow in Neuropathology, Harvard Medical School; Assistant Consulting Neurosurgeon, Children's Hospital, Boston; Research Fellow, Boston City Hospital.*

Separation of Growth-Promoting Hormone from that Inducing Premature Estrus in the Anterior Pituitary Gland..... 1699

Studies in Acromegaly: VIII. Experimental Canine Acromegaly Produced by Injection of Anterior Lobe Pituitary Extract..... 1708

LEO M. DAVIDOFF, M.D.

*Voluntary Graduate Assistant, Peter Bent Brigham Hospital, Nov. 1, 1923-March 1, 1924, and Oct. 6, 1925-Nov. 1, 1925; Surgical House Officer, ibid., March 1, 1924-June 20, 1925; Assistant Resident Surgeon, ibid., Nov. 1, 1925-Oct. 1, 1926. Research Assistant in Neuropathology, New York State Psychiatric Institute; Assistant in Clinical Surgery, New York Neurological Institute.*

Treatment of Hydrocephalus: Historical Review and Description of a New Method ..... 1737

R. G. SPURLING, A.B., A.M., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1923-March 1, 1925; Assistant Resident Surgeon, ibid., March 1, 1925-Sept. 1, 1925. Instructor in Surgery, University of Louisville School of Medicine; Attending Neurosurgeon to the Louisville City Hospital, Louisville, Ky.*

Cerebrospinal Fluid Changes in Composition and Drainage After Intravenous Administration of Various Solutions..... 1763

LYMAN RICHARDS, A.B., M.D.

*Associate in Otolaryngology, Peter Bent Brigham Hospital, June 12, 1924—Surgeon in Otolaryngology, Children's Hospital, Boston; Associate in Otolaryngology, Peter Bent Brigham Hospital, New England Baptist Hospital, New England Deaconess Hospital.*

Mastoiditis in Acute Nutritional Disturbance..... 1774

LESTER R. WHITAKER, M.D.

*Arthur Tracy Cabot Fellow, 1924-1925 and Associate in Surgery, Peter Bent Brigham Hospital, July 11, 1924-Sept. 1, 1925; Assistant Resident Surgeon, ibid., Sept. 1, 1925-July 1, 1927. Assistant in Surgery and Anatomy, Boston University School of Medicine; Second Assistant Visiting Surgeon, Massachusetts Homeopathic Hospital.*

Problems in Normal and in Abnormal Physiology of the Gallbladder.... 1783

SELLING BRILL, A.B., M.A., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1924-March 1, 1926. Hunter Fellow in Surgery and Assistant Instructor in the Department of Surgery, University of Pennsylvania Medical School; Assistant Surgeon to the Hospital of the University of Pennsylvania, Philadelphia.*

Glycogenolysis Due to Epinephrine in Hepatic Disease..... 1803

JOHN FALLON, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1925-July 1, 1926. Fellow in Surgery, the Mayo Foundation, Rochester, Minn.*

Hemolytic Streptococcal Subcutaneous Gangrene: Report of a Case..... 1817

THEODORE C. GREENE, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March 1, 1925-July 1, 1926. Surgeon, Douw Hospital, Presbyterian Mission, Peking, China.*

The Ability to Localize Sound: A Study of Binaural Hearing in Patients with Tumor of the Brain..... 1825

BURTON CLARK, JR., B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, May 1, 1925-Nov. 1, 1925. Preceptor, University of Wisconsin Medical School; Vice President of Staff and Instructor, Mercy and St. Mary's Hospitals, Oskosh, Wis.*

The University of Wisconsin Medical School: A Retrospect..... 1842

## FRANC D. INGRAHAM, M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1925-Nov. 1, 1926; Assistant Resident Surgeon, ibid., Sept. 15, 1927-September, 1928; Resident Surgeon, ibid., September, 1928-Oct. 1, 1928. Brigham Fellow at Oxford.*

- Local Morphologic Changes Following Section of the Thoracic Sympathetic Nerve Trunk..... 1857

## A. J. McLEAN, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1925-Nov. 1, 1926; Arthur Tracy Cabot Fellow, 1926-1927 and Associate in Surgery, Peter Bent Brigham Hospital, Jan. 10, 1927-Sept. 23, 1927; Assistant Resident Surgeon, ibid., Sept. 23, 1927—. Assistant Resident Surgeon, Peter Bent Brigham Hospital.*

- The Bovie Electrosurgical Current Generator: Some Underlying Principles and Results..... 1863

## GEORGES SCHALTENBRAND, M.D.

*Voluntary Graduate Assistant, Peter Bent Brigham Hospital, Oct. 6, 1925-March 1, 1927. Privatdozent for Neurology at the University of Hamburg; Associate in Neurology, Peking Union Medical College, Peking, China.*

- Muscle Tone in Man..... 1874

## JEAN MORELLE, M.D. (Louvain)

*Voluntary Graduate Assistant, Peter Bent Brigham Hospital, Oct. 6, 1925-September, 1926. Assistant to the Surgical Clinic, University of Louvain, Belgium.*

- Tumors of the Acoustic Nerve..... 1886

## CHARLES TEEL, M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Nov. 1, 1925-June 22, 1926. In Practice (Urology) Bellingham, Wash.*

- Diverticulum of the Bladder: An Analysis of Thirty-One Cases..... 1896

## J. I. BRADLEY, A.B., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, Nov. 1, 1925-March 1, 1927. Assistant in Pathology, Harvard Medical School; Assistant Pathologist, Massachusetts General Hospital.*

- Congenital Absence of the Vermiform Appendix..... 1904

## JOSEPH S. BARR, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1926-Nov. 1, 1927. Orthopedic House Officer, Children's Hospital and Massachusetts General Hospital.*

- Congenital Coxa Vara..... 1909

## WILLIAM J. GERMAN, A.B., M.A., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, July 1, 1926-Nov. 1, 1927. Assistant in Surgery, Yale Medical School; Assistant in Surgery, New Haven Hospital.*

- The Effect of Some Antiseptics on Tissues in Vitro..... 1920

LOUISE EISENHARDT, M.D.

*Voluntary Graduate Assistant, Peter Bent Brigham Hospital, Sept. 17, 1926-March 8, 1928; Junior Associate in Surgery, ibid., March 8, 1928—Junior Associate in Surgery, Peter Bent Brigham Hospital; Lecturer on Hygiene, Simmons College (School of Public Health).*

The Operative Mortality in a Series of Intracranial Tumors..... 1927

HUGH CAIRNS, M.B., B.S., Univ. of Adelaide.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Oct. 1, 1926-Sept. 15, 1927. Assistant Surgeon to the London Hospital.*

Observations on the Localization of Intracranial Tumors: The Disclosure of Localizing Signs Following Decompression or Ventriculography ..... 1936

JOHN H. POWERS, A.B., B.A. (Oxon.), M.D.

*Assistant Resident Surgeon, Peter Bent Brigham Hospital, Oct. 15, 1926-Sept. 15, 1927; Arthur Tracy Cabot Fellow, Sept. 15, 1927-1928 and Associate in Surgery, Peter Bent Brigham Hospital, Sept. 15, 1927-1928; Resident Surgeon, ibid., Oct. 1, 1928—. Resident Surgeon, Peter Bent Brigham Hospital; Assistant in Surgery, Harvard Medical School.*

The Experimental Production of Mitral Stenosis..... 1945

The Relationship of the Toxin of *Bacillus Welchii* to the Toxemia of Intestinal Obstruction..... 2019

JOHN E. SCARFF, B.S., M.D.

*Surgical House Officer, Peter Bent Brigham Hospital, March, 1927-July 1, 1928; Assistant Resident Surgeon, ibid., July 1, 1928—. Assistant Resident Surgeon, Peter Bent Brigham Hospital.*

The Experimental Production of Pulmonary Abscess: Etiologic Factors. 1960

IGNAZ OIJENICK, Med. Docts. Arts.

## THE SO-CALLED HOUR-GLASS TUMORS OF THE SPINE

GEORGE J. HEUER

The experience some years ago of finding at operation on a paraplegic patient a circumscribed extradural spinal tumor, the narrowed pedicle of which proceeded through an enlarged intervertebral foramen to be continuous with a larger growth in the posterior mediastinum, has led to a continued interest in the so-called hour-glass or dumb-bell tumors involving the spinal cord. My first patient was seen and operated on in 1916, and only recently have two others come under my observation. To the comparatively few who have personally observed them at the operating or autopsy table, these tumors are well known; to the great majority of physicians and surgeons they are apparently quite unknown. They have a very general interest, for while they implicate the cord eventually and are therefore more often seen by the neurologist and neurosurgeon, their paravertebral portions may present in the neck or back to confuse the general surgeon just as they may present in the thorax, the abdomen and the pelvis. They are not so uncommon as the literature would indicate, and one has only to read case reports of spinal tumors to discover that they have not infrequently been observed but have failed to excite comment. They deserve perhaps to be recognized as a clinical group, for while their pathologic processes may vary, they arise from a restricted region in or about the spine, show peculiar tendencies in their growth and often give rise to distinctive signs and symptoms.

### DEFINITION

The term "hour-glass tumors" is applied to a group of tumors which arise along the spine from the highest cervical to the lower sacral vertebrae, either from within the spinal canal (ganglions, nerves, dura, vertebral ligaments), from the vertebrae (cartilage of intervertebral disks) or from without the spine (sympathetic chain, ribs, fascia). Arising intraspinally, they have been thought to grow outward through an intervertebral foramen or between two adjoining laminae to form an extra or paravertebral tumor; or arising paravertebrally, they have been thought to extend through an intervertebral foramen into the spinal canal to form there an intraspinal growth. At the point where they penetrate the intervertebral foramina the tumors are constricted and assume, therefore, an hour-glass shape (fig. 1). The term has been used to include tumors which are entirely intraspinal but which are both intradural and extradural. Arising either within or without the dura,

they penetrate this membrane usually at the site of exit of a spinal nerve, at which point they are constricted and assume an hour-glass shape. It is to be noted that the intervertebral foramina occupied by tumor tissue are usually enlarged as if by pressure atrophy of the bone rather than by invasion of the bone. The term hour-glass tumors has not been applied to the not uncommon malignant tumors (sarcoma, metastatic carcinoma, etc.) which invade and destroy the vertebrae and involve the spinal cord, and I have not considered such tumors in this paper.

#### LITERATURE

The literature on hour-glass tumors is meager. With the exception of the articles by Antoni, Guleke, Borchardt and Coenen, I have failed to find any direct reference to this group of tumors. Antoni, in his monograph on tumors of the spinal cord (1920), devoted a chapter to them, reported three cases of his own and collected twenty cases from the literature. Since Antoni's paper, Guleke has reported four cases in addition to the one included in Antoni's series. Borchardt, in 1926, reported three cases. In an attempt to gather together what I was convinced is not so rare a form of tumor as the literature would indicate, I have read the case reports, when such have been presented, of the larger series of tumors of the cord reported in the past ten to fifteen years, and in addition, I have reviewed the literature, particularly on the tumors of the spine, of the ribs and of the sympathetic nervous system. It becomes apparent from such a study that hour-glass tumors have repeatedly been observed and reported, frequently without comment, occasionally with some reference to their peculiar growth. For example, Elsberg in 100 cases of tumors of the cord has seen 6; Dandy in 36 consecutive cases has observed 6, and others 1 or 2. From various sources, then, I have collected 41 cases (including 3 of my own) since Antoni's report in 1920, making the total 64. In addition to these, there are 5 or 6 cases of enchondroma of the spine, which according to Valentine were of the hour-glass variety but the references were not available to me, and 11 cases which because of incomplete descriptions are doubtful. I am sure that many more cases which I have failed to discover lie buried in the literature.

#### PATHIOLOGY

At first glance it appears that the hour-glass tumors include a great variety of pathologic conditions. But closer study shows that they arise from a fairly restricted region and pathologically include only a limited number of tumors. Of the sixty-four cases of hour-glass tumors which are fairly definite, six are called neurinomas; twelve, neurofibromas; five, neuromas; six, fibromas; five, ganglioneuromas arising from the sympathetic chain; one, lipoma; four, chondromas; seven, fibrosarcomas; ten, sarcomas (seven sarcomas, one giant cell sar-

coma, one psammosarcoma, one angiosarcoma) ; and one each a spongioblastoma, malignant neuroblastoma, chondrosarcoma, leiomyoma and "congenital tumor." In three cases, the pathologic diagnosis is not stated but such descriptions as are given suggest in two an origin from the dura or nerves. The neurinomas, neurofibromas, neuromas and fibromas are almost certainly of neurogenic origin. In all probability a goodly number of the fibrosarcomas and sarcomas reported have had a similar origin, and whether they were true sarcomas or forms of endothelioma or fibroma is questionable. The fact that there was in some complete cure or failure of recurrence over long periods follow-

Fig. 1.—Hour-glass tumor compressing the spinal cord and extending into the mediastinum; case 4 under Tumors of the Dorsal Region (Guleke).

ing removal does not of itself speak against sarcoma, but does suggest a benign form. Similarly, the question arises whether certain other tumors are not of neurogenic origin. The tumor called a giant cell sarcoma might well be a neuroma, for others (Dandy and others) have observed similar tumors with giant cells. The tumor called psammosarcoma might be classed with the tumors described by Naffziger as psammofibroblastoma. The congenital tumor described by Dandy may have had a neurogenic origin. The leiomyoma may well be a neurinoma as suggested by Borchardt. The cases of spongioblastoma and malignant neuroblastoma are certainly of neurogenic origin. In all likelihood the large majority of the hour-glass tumors have had an origin from the membranes of the cord (dura, particularly)

or from the ganglions and nerve roots. That true sarcomas have occurred in this series is, however, undoubted and it is not implied that the hour-glass tumors are all benign. Such malignant tumors may have arisen from the ligaments of the vertebrae and from the adjacent paravertebral fasciae, although the point of origin is not often clearly stated. Five of the hour-glass tumors are ganglioneuromas arising from the sympathetic nervous system. Five are chondromas (one chondrosarcoma) arising from the intervertebral disks (an unlikely origin according to some), articular surfaces of the vertebrae or heads of the ribs. One is a lipoma (three of the eleven doubtful cases also are lipomas) arising apparently from the epidural fat. It thus appears that the hour-glass tumors thus far described have arisen from the membranes, the ganglions and nerve roots of the spinal cord, from the ligaments and fasciae in or about the vertebrae, from the cartilage of the articular surfaces of the vertebrae and ribs, from the intraspinal epidural fat and from the sympathetic nervous system. The great majority of these tumors have been benign, encapsulated growths; a few have been definitely malignant.

For the purpose of further discussion these tumors may be conveniently grouped according to the region in which they occurred into cervical, dorsal and lumbosacral tumors. Of the sixty-four cases, eighteen occurred in the cervical, thirty-seven in the dorsal and eight in the lumbosacral region. In one case (Antoni), the condition was general, and multiple tumors occurred throughout the length of the cord.

#### TUMORS IMPLICATING THE CERVICAL SPINAL CORD

A study of the eighteen cases of cervical hour-glass tumors shows that twelve are grouped pathologically as neurinomas, fibromas, neurofibromas and fibrosarcomas. One is called a leiomyoma; one, a congenital tumor, and two, sarcomas. In two cases, the diagnosis is not given, but in both the tumors were circumscribed. In only one of the series (Hildebrand, sarcoma) was the tumor such that it could not be completely removed from the spinal canal. It is apparent, therefore, that almost invariably the tumors were benign encapsulated growths.

In anatomic relation to the spinal cord, spine and paravertebral structures, these tumors fall into several groups:

(a) *Intraspinal Tumors*.—This type of tumor lies within and without the dura, the constricted portion of the tumor being at the point where the tumor penetrates the dura with a nerve root. The tumors did not extend into the intervertebral foramen nor were they associated with a paravertebral tumor. Three cases belong to this group.

(b) *Intraspinal (Both Intradural and Extradural), and Paravertebral Tumors*.—These tumors lie within and without the dura, extending

through the intervertebral foramen and being connected with a tumor of the neck or mediastinum. In this group there are two points of constriction, one where the tumor penetrates the dura, the other where it occupies the intervertebral foramen. Five cases belong to this group.

(c) *Intraspinal (Extradural Only), and Paravertebral Tumors.*—These tumors are extradural with relation to the spinal cord and connected with a process which occupies the intervertebral foramen and which in turn is connected with a tumor of the neck. Ten cases occur in this group (figs. 2, 3 and 4).

Of the eighteen cases, therefore, in three the tumor was confined entirely to the intraspinal canal. In the remaining fifteen cases, the tumor was both intraspinal and paravertebral. Of these, the para-

Fig. 2—Hour-glass tumor ("Cervical Neurofibroma") of the cervical region presenting a tumor of the neck; case 14 under Tumors of the Cervical Region (Elsberg). Photograph of patient shown in figure 11.

vertebral tumor occurred in the neck in fourteen instances and in the superior mediastinum in one instance. Of the fourteen tumors of the neck, eleven were visible and palpable tumors, presenting in the anterior or posterior triangles of the neck from the mastoid region to the clavicle; three were not discovered before operation or autopsy but judging from the size of the tumors in two of the cases, they should have been easily palpable in the supraclavicular space.

The size of the intraspinal tumors, whether intradural or extradural, or both, has naturally varied within narrow limits according to the size of the spinal canal. The majority are described as small (i.e., the size of a hazelnut); a few at the lower end of the spinal canal were larger (i.e., the size of a walnut). In the majority of instances they have been

firmly elastic, encapsulated growths compressing but not otherwise implicating the cord. Their attachments have varied; in some instances they have been firmly attached to and appeared to arise from the dura; in other instances they have been attached to or appeared to arise from the nerve roots or ganglions, and in still other instances they have had no apparent connection with the dura, nerves or ganglions.

The paravertebral tumors have shown a greater variation in size—from that of a plum to that of an orange. As previously noted, eleven

Fig. 3.—Hour-glass tumor of cervical region presenting a large tumor of the neck; autopsy specimen; case 15 under Tumors of Cervical Region (Flateau and Sawicki).

of the fourteen paravertebral tumors which occurred in the neck were visible and palpable. They presented in the anterior or posterior triangles of the neck from the mastoid region to the clavicle, were spherical or elongated, and were hard and elastic. Some of the tumors were superficial, circumscribed and freely movable; others were deeply situated beneath the sternomastoid, more or less indefinite in outline, and rather fixed. They occasionally impinged on the brachial plexus and other nerves without involving them, but in two instances they were formed by the tumorous enlargement of a cord of the brachial

plexus. In these two instances the paravertebral tumor was not discovered before operation or autopsy, but probably would have been had a careful examination been made. In a third case, a soft, gelatinous tumor the size of a walnut lay against the second and third cervical vertebrae, and was found only at autopsy. In the single instance of paravertebral mediastinal tumor in this group, the tumor was sufficiently large to cause dulness in the apical region and to cast a definite shadow in the x-ray film.

Fig. 4.—Hour-glass tumor of the cervical region presenting a large tumor of the neck; dissection of tumor at autopsy (Fleteau and Sawicki).

#### TUMORS IMPLICATING THE DORSAL SPINAL CORD

Of the thirty-seven cases in this group the neuromas (five), the neurinomas (five), neurofibromas (six), and fibrosarcomas (five) comprise twenty-three and have evidently had their origin from the membranes of the cord, the nerves and the ganglions. Five of the thirty-seven are ganglioneuromas arising from the sympathetic chain, five are chondromas (one called a chondrosarcoma) arising from the cartilage structures of the vertebrae and ribs, and three are sarcomas,

the origin of which is indefinite. In one case, the pathologic diagnosis is unknown. Of the three tumors called sarcomas, two (Guleke and Brunschweiler) were hard encapsulated growths adherent to the dura but easily separated from this membrane, and one (Dandy) was called an angiosarcoma, the intraspinal portion of which apparently disappeared under radium therapy and the mediastinal part of which failed to show any increase in size over a five year period of observation. It is evident, therefore, that the large majority of the tumors in this group also were benign.

Following the classification used in describing the cervical tumors, the thirty-seven dorsal tumors fall into the following groups:

- (a) Intradural and extradural only, five cases.
- (b) Intradural and extradural and paravertebral, two cases.
- (c) Extradural and paravertebral, twenty-eight cases.
- (d) Paravertebral and foramenal (no proved intraspinal tumor), two cases.

Of the thirty-seven cases in this group, therefore, five were associated with tumors which were confined entirely to the intraspinal canal. In the remaining thirty-two cases, the tumor was both intraspinal and paravertebral (thirty cases) or paravertebral only (two cases). In the two cases classed as paravertebral and foramenal, the tumor occupied the mediastinum and presented a pedicle or process which entered the intervertebral foramen, but failed to have an intraspinal tumor sufficiently large to cause compression symptoms of the cord (figs. 5 and 6). Of the thirty-two cases in which paravertebral tumors were present, these presented in the back alone in three cases (fig. 7), in the mediastinum alone in twenty-five cases (fig. 8), and in both back and mediastinum in four cases (fig. 9). In the last group the paravertebral tumor was divided into two portions, one of which lay in the muscles of the back, the other in the posterior mediastinum. Of the seven cases in which tumors of the back occurred, these were visible or palpable in four instances, and not palpable or not noted to have been palpable in three instances (operative or autopsy observations). In the twenty-nine cases in which mediastinal tumors were present, positive roentgen evidence of the tumor was recorded in sixteen. In only one case roentgen examination failed to show a tumor subsequently found at operation or autopsy. In twelve cases there are no records that roentgenograms of the chest were taken. It is probable that in the great majority of cases the roentgenograms would have demonstrated the tumor if careful x-ray studies had been made.

In thirty-five of the thirty-seven cases an intraspinal tumor was present and caused compression symptoms of the cord. In two cases an intraspinal tumor was either absent, or at least failed to cause compression symptoms. In these two cases a laminectomy was not performed, and the true condition present remains doubtful. The intraspinal tumors

were in general small, the largest recorded being 4 by 2 cm. in diameter. Almost without exception they are described, when descriptions are given, as hard, circumscribed, encapsulated tumors. Not infrequently they have been attached to the dura, but usually have been separable from this structure. In four instances a nerve is described as entering

Fig. 5.—“Pedunculated neurinoma” (analogous to hour-glass tumor) of the posterior mediastinum; case 5 under Tumors of Dorsal Region (Guleke).

Fig. 6.—Diagram of the location of the pedunculated neurinoma; shown in figure 5 (Guleke).

and being lost in the tumor; in four they have been stated to have arisen from the ganglions. Often no attachments of the tumor, if any were present, are noted.

The paravertebral tumors have varied in size from that of a plum to that of a lemon. They have extended into the muscles of the back,

pushing the muscles aside, and have been hard, elastic, circumscribed, encapsulated tumors without invasive tendencies. The paravertebral mediastinal tumors have been described as varying in size from that of a plum to that of an infant's head. These, too, have been circumscribed tumors separable, as a rule, from the pleura. In the entire series of thirty-seven cases I have found but one in which at autopsy there was evidence of extension or metastasis of the tumor. In this case (Banse) tumor nodules were found in the spleen and portal vein.

Fig. 7.—Hour-glass tumor of the dorsal region presenting a paravertebral extension into the muscles of the back; case 4 under Tumors of the Dorsal Region (Guleke).

#### TUMORS IMPLICATING THE LUMBOSACRAL CORD

Included in this smaller group of eight cases are one neurinoma, one fibrosarcoma, one lipoma, one ganglioneuroma, one spongioblastoma, one malignant neuroblastoma and two sarcomas. Four of the eight cases are, therefore, classed as malignant tumors. They were, however, so far as I can determine, circumscribed tumors which neither invaded the structures of the cord nor the muscles of the back. The case of lipoma is the only instance of this variety of tumor in the entire series, but I have found three or four doubtful cases of this variety of growth. The analogy between the hour-glass lipomas of the cord and those of the thorax will be discussed in a subsequent paragraph.

Fig. 8.—Semidiagrammatic representation of an hour-glass tumor of the dorsal region presenting a large mediastinal tumor; case 26 under Tumors of Dorsal Region (Borchardt).

Fig. 9.—Hour-glass tumor of dorsal region after removal; *a*, portion occupying the vertebral canal; *b*, portion extending into the muscles of the back; *c*, portion occupying a pocket in the vertebra; *d*, portion in the posterior mediastinum; case 4 under Tumors of Dorsal Region (Guleke).

Anatomically the eight cases fall into the following groups:

- (a) Intradural and extradural only, two cases.
- (b) Intradural and extradural and paravertebral, two cases.
- (c) Extradural and paravertebral, four cases.

Of the eight tumors in this group, therefore, two were entirely intraspinal although one of these presented a process which extended into the intervertebral foramen. Six were both intraspinal and paravertebral. Of the six paravertebral tumors, these presented in the back in three instances, in the abdomen (retroperitoneal) in two instances, and in the pelvis in one instance. Of the three tumors of the back, two were visible and palpable; one gave no evidence of its presence before operation. Of the two intra-abdominal tumors (retroperitoneal), neither apparently was recognized before autopsy. The pelvic tumor was palpable per rectum, and its pedicle could be followed into an intervertebral foramen.

The intraspinal tumors varied in size from that of a hazelnut to that of a walnut. As in the other groups they were circumscribed, encapsulated growths. The paravertebral tumors varied from a "ten pfennig piece" (palpable per rectum) to an enormous tumor of the back. One of the retroperitoneal tumors is described as the size of a man's fist. These also were circumscribed growths. In one case of retroperitoneal tumor, however, nodules, presumably extensions or metastases, were found at autopsy in the adjoining mesentery.

#### MULTIPLE OR GENERALIZED HOUR-GLASS TUMORS OF THE CORD

The single instance of multiple hour-glass tumors in this series occurred in the case of Antoni. The history and symptoms are briefly outlined in the abstract of the case report. At autopsy, multiple spinal tumors were found distributed along the cord, but those in the cervical region are of particular interest for present purposes (fig. 10). Every posterior spinal nerve root had a tumor intimately associated with it, these tumors being both intradural and extradural and constricted at the point where they penetrated the dura. A tumorous enlargement of the spinal nerves distal to the growths occupied each enlarged intervertebral foramen. Paravertebral tumors were present in the neck (brachial plexus) and in the mediastinum, where masses of tumors resembled an advanced lymphosarcomatosis.

#### ORIGIN AND DIRECTION OF GROWTH

An attempt has been made in the preceding pages to determine the origin of the hour-glass tumors and with only partial success. It can, however, be stated that they arise from the membranes, nerves and

ganglions of the cord, from the sympathetic nervous system, from the ligaments in or about the vertebrae, from the cartilage of the articular surfaces of the vertebrae and ribs, and rarely from the epidural fat. The larger number have arisen from the membranes, nerves and ganglions of the cord. A matter even more obscure are the factors determining their shape and their growth. Various authors commenting on their particular cases have expressed the opinion that the tumors have arisen within the spine, have grown outward or extended through an intervertebral foramen and have enlarged again in the paravertebral structures. Others have believed that the tumors arose without the spine

Fig. 10.—Specimen from patient with neurofibromatosis presenting symptoms of cord compression; multiple neurofibromas of the hour-glass type in the cervical region (Antoni).

and grew through an intervertebral foramen to enlarge again in the intraspinal space. A third group of observers have expressed the opinion that the tumors have arisen within the intervertebral foramen and have grown in both directions; this is a more plausible view than the preceding two since the tumors in this instance would be growing in the line of least resistance. Still a fourth and later view (Coenen) is that these tumors take a passive, not an active, part in the determination of their shape; that they are present as tumors, possibly as spherical tumors, before the development of the spine, and that the spine

in its development impinges on the tumors and constricts them and so gives them their hour-glass shape.

In a consideration of these theories it is interesting to seek analogies to the hour-glass tumors of the cord in other parts of the body. (a) In a description of the intrathoracic lipomas<sup>1</sup> I have called attention to five or six cases in which the tumor has presented an intrathoracic and extrathoracic enlargement connected by a constricted portion which occupied a perforation in the thoracic wall between two ribs. Coenen has called attention to the same group and has added the case of Harms. These are, then, hour-glass tumors similar to those of the spinal cord. (b) Certain of the fibrolipomas of the spinal cord associated with spina bifida occulta present similar characteristics. In a recent case a colored man presented a visible and palpable tumor over the lower end of the spine, a spina bifida occulta, a bilateral congenital clubfoot, trophic ulcers over the external aspect of the foot and perineum and sensory disturbances over the legs. At operation, a large fibrolipoma was found with a distinctly hour-glass shape. The outer part of the tumor lay under the skin and subcutaneous tissues, and the inner part occupied the enlarged spinal canal. Connecting the two was a constricted portion which closely filled the circular defect in the spine. (c) Certain of the dermoid cysts of the head are also similar. A child was seen recently whose parents had noted soon after birth a swelling over the occiput. On examination, there was a visible and palpable tumor under the scalp in the occipital region which narrowed to a pedicle. This pedicle seemed to disappear into a circular hole in the skull. The roentgenogram of the skull confirmed the bony defect. At operation, a dermoid cyst was found which was made up of an intracranial and extracranial part connected by a constricted portion which occupied the circular defect in the skull. (d) Other analogous conditions might be mentioned, i.e., the rather rare upper epigastric hernia which apparently perforates the xiphoid, and the persistent thyroglossal duct which apparently perforates the hyoid bone.

In these various conditions somewhat similar factors as regards the growth and shape of the tumors must obtain. It is a question whether an hour-glass tumor of the cord arising within the spinal canal would grow outward through an intervertebral foramen rather than follow a line of lesser resistance along the cord, or arising paravertebrally would grow inward through a foramen rather than enlarge paravertebrally. Similarly, it is a question whether a soft tumor like a lipoma arising either within or without the thoracic cage would perforate the rigid wall of the chest rather than grow locally within or without the thorax.

---

1. Heuer: Thoracic Tumors, in Lewis Dean: Practice of Surgery, Hagerstown, Md., W. F. Prior Co., 1928; Surgery of the Thorax, in Nelson's Loose-Leaf Surgery, New York, Thomas Nelson & Sons, 1928.

The same question applies to the dermoid cysts of the head whether they apparently perforate the skull in the occipital or temporal regions. The thought occurs, then, as Coenen suggests, that the tumors are laid down as such before the complete development of the skeleton and that they are impinged on and constricted so as to assume an hour-glass shape by the growth of the skeleton. In the foregoing case of spina bifida occulta in which the constricted portion of an hour-glass tumor occupied the defect in the spine, it would appear more likely that the failure of fusion of the laminae was due to the interposition of a fibrolipoma which antedated the fusion of the laminae than that a fibrolipoma just happened to occupy an unexplained defect in the spine.

The questions of the factors determining the shape and direction of growth of these tumors cannot be settled with the data available at the present time. It would, however, appear to me that Coenen's idea has much to recommend it and serves to explain certain characteristics of these tumors otherwise difficult of explanation.

#### SYMPTOMATOLOGY

There is little to be said about the symptomatology and the clinical signs of the hour-glass tumors. The outspoken symptoms, with only two exceptions, have been those due to compression of the spinal cord and have differed in no way from those of other tumors of the spinal cord. They need not again be detailed. They have either almost completely overshadowed other symptoms or other symptoms have been strikingly absent. In the group of hour-glass tumors of the cervical region, tumors of the neck, as previously noted, were visible and palpable in eleven cases, and were present but not palpable in three cases. Aside from their presence, these tumors failed to give rise to any noteworthy symptoms. They were slow growing, painless tumors. The single mediastinal tumor in this group was large enough to give physical signs (dulness on percussion over the apical region) and cast a shadow in the x-ray plate but was unassociated with symptoms.

In the group of hour-glass tumors of the dorsal region, tumors of the back were present in seven cases and tumors of the mediastinum in twenty-nine cases. Four of the seven tumors of the back were visible or palpable; three were discovered only at operation or autopsy. Pain in the back was complained of in some cases, but was no doubt rightly ascribed to the cord lesion. Except for pain, there were no symptoms with reference to these tumors. Of the twenty-nine mediastinal tumors, eleven were associated with symptoms such as pain in the back (five cases), pain in the abdomen and side (five cases), and cough and dyspnea (two cases). The pain in the back and abdomen may well have been the result of the spinal rather than of the mediastinal tumor. In nine cases there were no symptoms referable to the mediastinal tumor,

and in nine there are no records of symptoms. Physical signs, such as dulness on percussion, were present in four cases, absent in sixteen and not stated in nine. A roentgenogram of the chest positively demonstrated the mediastinal tumor in sixteen cases and failed to show it in one case. In twelve cases there are no records of roentgen examinations. The absence of thoracic symptoms is probably due to the facts that mediastinal or intrathoracic tumors generally may fail to provide symptoms unless they implicate certain important structures, and that the tumors in this group of cases were usually small. Although the size of the tumors is not always stated, it would appear that only four (Guleke, Dandy, Heuer, Stout) were large.

In the group of hour-glass tumors of the lumbosacral region, tumors of the back were present in three cases, of the abdomen in two cases of the pelvis in one case. Two of the three tumors of the back were visible and palpable, but as a group they were without symptoms. The two patients with retroperitoneal intra-abdominal tumors were apparently without symptoms, and the tumors were not discovered during life. In the case of pelvic tumor there were no symptoms, but the tumor was palpable on rectal examination.

#### DIAGNOSIS

Recognition of the true nature of the hour-glass tumors has been rare. The symptoms of cord compression have, of course, been recognized and the diagnosis of tumor of the cord has almost invariably been made; but in the past, at least, the association between the tumor of the cord and a tumor of the neck, the back or the mediastinum, has only been recognized at the operating or autopsy table. More recently, observers especially interested in the subject (Guleke, for example) and on the outlook for this condition have made positive diagnoses. The most important matter in the diagnosis of the hour-glass tumors is the recognition of the fact that these tumors occur. Granted this, the presence of symptoms of tumor of the cord combined with the presence of a paravertebral tumor at a level corresponding with that of the tumor of the cord strongly suggests an hour-glass tumor. The routine examination of patients with possible tumors of the cord should include not only a careful neurologic examination but also, depending on the level of the spinal lesion, a careful examination including a roentgenogram of the neck, the thorax, the back, the abdomen and the pelvis. Otherwise, a paravertebral tumor may well be missed.

#### TREATMENT

In 1925, Elsberg stated that "up to recent years, an extradural tumor that was an extension inward of a growth in the soft tissues of the back or in the posterior mediastinum, or that, vice versa, had

extended outward into the soft parts of the back or between the ribs was considered irremovable." This point of view, as Elsberg rightly stated, will have to be changed. Indeed it has been changed, and more and more of the hour-glass tumors are being attacked successfully. I have attempted to show that the great majority of hour-glass tumors of the spinal cord thus far reported are benign, encapsulated, enucleable growths and lend themselves satisfactorily from this standpoint to operative removal. The technical difficulties attending their removal are by no means insurmountable, nor is the operation necessarily severe. Depending on the patient's condition, the operation may be done in one or two stages, and the two-stage operation will undoubtedly come into question if the paravertebral tumor be especially large or its removal likely to be attended with difficulties. In small paravertebral tumors, whether these lie in the neck, mediastinum or back, a one-stage operation is probably desirable.

The primary attack should, I think, be directed to the spinal tumor (laminectomy) if spinal cord symptoms are present, not only because of the urgency of these symptoms but also because experience has shown that often the paravertebral tumors of the back, the neck or the mediastinum may be removed through the operative wound intended for the removal of the spinal tumor. A review of the operative experiences in the treatment of the hour-glass tumors is helpful in determining the method of approach and brings forth some interesting observations.

Of the eighteen patients with hour-glass tumors of the cervical region, eleven were subjected to operation; seven died without an operation having been performed and came to autopsy. The eleven patients subjected to operation may be grouped as follows:

(a) Primary operation directed toward the removal of the intraspinal tumor, five cases:

(1) In one case a paravertebral tumor was not present (intradural and extradural only).

(2) In one case a paravertebral tumor (tumor of the neck) was not discovered at operation but was observed at autopsy.

(3) In one case the paravertebral tumor (tumor of a cord of the brachial plexus) was not removed.

(4) In one case the tumor of the neck was removed together with the intraspinal tumor through the laminectomy wound.

(5) In one case a paravertebral tumor was not apparent at the time, although a pedicle of the extradural tumor entered the intervertebral foramen. This was tied off. Nine years later, the patient presented herself to another surgeon with a large visible tumor of the neck and with a recurrence of cord symptoms. At a second operation, nine years after the first, a tumor the size of a lemon was removed from beneath the main blood vessels of the neck. It narrowed to a pedicle 2 cm. in

diameter which entered an intervertebral foramen. There was again the recovery from the cord symptoms.

(b) The primary operation directed toward the removal of the tumor of the neck, five cases:

(1) In two of the cases there were apparently no spinal cord symptoms present at the time of the removal of the tumor of the neck. These appeared a short time after the first operation. In both cases a process of the tumor extending into the intervertebral foramen was observed at the primary operation. Both patients were later subjected to a laminectomy, and the spinal tumor removed.

(2) In two cases spinal cord symptoms were present but the primary operation, nevertheless, consisted in the removal of the tumor of the neck. In one, the intraspinal tumor was removed through the enlarged intervertebral foramen by the help of traction on the pedicle of the tumor of the neck. In the other, traction on the pedicle which disappeared into the intervertebral foramen was followed by a sudden gush of cerebrospinal fluid. The pedicle was tied off and the operation abandoned. (The patient recovered from the spinal cord symptoms.)

(3) In one case with spinal cord symptoms, the primary operation again consisted in the removal of the tumor of the neck. The pedicle entering the intervertebral foramen was tied off. Ten days later, a laminectomy was done and the intraspinal tumor removed.

(c) The primary operation directed toward the removal of a mediastinal tumor, one case:

The patient presented cord symptoms, dulness over the right apex of the lung and a mediastinal shadow in the x-ray films. The mediastinal tumor was apparently without symptoms. It was removed in two stages. During the second operation, and after the removal of the mediastinal tumor, a laminectomy was done but no spinal tumor found. The patient died, and the intraspinal tumor was found at a higher level at autopsy.

Of the thirty-six patients with hour-glass tumors of the dorsal region, twenty-nine were subjected to operation; eight died without an operation having been performed, of which seven came to autopsy. In some of the eight cases data are lacking, so that this statement may not be correct literally. In the eight cases, two patients had pressure sores which prevented a laminectomy and one entered the hospital unconscious and died before a diagnosis had been made. The twenty-nine patients who were subjected to operation may be grouped as follows:

(a) The primary operation directed toward the removal of the tumor of the cord, twenty-five cases:

(1) In three cases no paravertebral tumor was present and the operation consisted simply in the removal of the intradural and extradural tumors.

(2) In seventeen cases the tumors of the cord, the mediastinal tumors and the tumors of the back were all removed through the primary laminectomy incision at one sitting. The removal of the mediastinal tumors sometimes required the resection of the transverse processes of the vertebrae and the articular ends of one or more ribs, but this was accomplished without great difficulty through the posterior incision.

(3) In four cases the primary laminectomy was terminated with the removal of the tumor of the cord only, and the mediastinal tumors were left untouched; nor was the mediastinal tumor subsequently removed, so far as the records indicate, in the one patient who survived. In three of the four cases death followed soon after the laminectomy, and it is presumed that the patients' condition made necessary the termination of the operation.

(4) In one case the primary operation consisted in the removal of the tumor of the cord. One month later, a thoracotomy was performed and the mediastinal tumor removed. The two operations were performed by different surgeons.

(b) The primary operation directed toward the removal of the tumor of the mediastinum (three), or back (one):

(1) In two of the three cases of mediastinal tumor, there were no cord symptoms at the time of operation and the rationale of the procedure was sound.

(2) In the third case, cord symptoms were present, but the mediastinal tumor was explored first. It appeared inoperable, and both it and the cord lesion were treated by radium. The cord symptoms disappeared but the shadow of the mediastinal tumor remained the same. Five years afterward, the patient was free from symptoms.

(3) In the one case in which a tumor of the back and loin was removed at a primary operation, the cord symptoms markedly improved, and it was presumed that the removal of the paravertebral tumor allowed sufficient dislocation of the tumor of the cord to relieve the cord symptoms. The late results in the case are not known.

Of the eight patients with hour-glass tumors of the lumbosacral region, five were subjected to operation; three apparently were not operated on and came to autopsy. The five cases in which operation was performed may be grouped as follows:

(a) The primary operation directed toward the removal of the tumor of the cord, four cases:

(1) In one case no paravertebral tumor was present and the operation consisted in the usual laminectomy with removal of the tumor of the cord.

(2) In two cases the paravertebral tumors (tumor of the pelvis; tumor of the back) were removed through the primary laminectomy incision.

(3) In one case neither the tumor of the cord nor the tumor of the back was removed. The tumor was considered inoperable.

(b) The primary operation directed toward the removal of the tumor of the back, one case:

The patient died following the removal of this tumor, and the tumor of the cord was found at autopsy.

The patient with multiple hour-glass tumors was subjected to operation, the operation consisting in a laminectomy for the relief of pressure symptoms of the cord. The tumor of the cord was removed. The patient died, and the multiple tumors were found at autopsy.

*Summary of Operative Treatment.*—The foregoing analysis would suggest the following remarks:

1. In the hour-glass tumors of the cervical region associated with paravertebral tumors, the primary approach should be directed to the removal of the tumor of the cord, but chiefly because of the urgency of the cord symptoms. The feasibility of removing a paravertebral tumor of the neck or mediastinum through the laminectomy incision and at the same sitting will depend on the location of the paravertebral tumor. If its location is such as not to lend itself easily to removal through the laminectomy incision, it is perhaps better to remove it through another incision either at the same time or at a subsequent sitting. In the past experience, only one of the paravertebral tumors has been removed through the primary laminectomy incision (Elsberg). In another case removal was possible but the tumor was not discovered. The interesting experience of Elsberg and Rixford (case 13, under "Tumors of Cervical Region"), in which a tumor of the neck and the recurrence of cord symptoms appeared eight or nine years after the original laminectomy, suggests the careful removal in all cases of that portion of the tumor occupying the paravertebral foramen, for it is possible that this is the site of origin of the tumor and of recurrence.

2. In the hour-glass tumors of the dorsal region associated with paravertebral tumors, the primary approach again should be directed to the removal of the tumor of the cord, not only because of the urgency of the cord symptoms but because of the possibility of removing, through the primary incision and at the same time, the paravertebral tumor. In twenty of the twenty-nine patients subjected to operation, the operation was completed at one sitting, in seventeen of which a tumor of the mediastinum or of the back was removed with the tumor of the cord. From a survey of the reported cases there seems no good reason for

attacking the mediastinal tumor primarily. In only two cases in which at the time there were no cord symptoms did the procedure appear rational.

3. What has been said of the hour-glass tumors of the dorsal region applies equally to those of the lumbrosacral region. A primary laminectomy may permit the removal, through the same incision and at the same time, of a tumor of the back or pelvis. An exception may well be the occasional retroperitoneal tumor, which if discovered may have to be approached through an abdominal incision.

*Results.*—Of the sixty-four cases assembled, forty-six of the patients were operated on; eighteen were either not operated on or data regarding operation were missing in the reports available to me. Of the eighteen patients, all died and seventeen came to autopsy.

Of the forty-six patients operated on in one or two stages, thirty recovered and nine died. In seven, the result is not stated. Of the nine patients who died following the operation, three died of complications (meningitis from cerebrospinal fistula, empyema followed by meningitis, pneumonia). The mortality rate, therefore, has been rather high, but it is to be remembered that a number of cases date back a good many years. Of the thirty patients who recovered, there was complete or almost complete disappearance of the cord symptoms in twenty-three, improvement in the cord symptoms in three, no improvement in two, and an unknown result in one. In one patient operated on primarily for a mediastinal tumor and in the absence of cord symptoms, there was improvement in the thoracic pain.

The records of late results leave much to be desired. In twenty-one of the thirty cases, the late results are not given. Three patients were well from three to twelve years, one of whom after five years still presented a symptomless intrathoracic tumor. Two patients were improved at the expiration of five years, but retained residual symptoms. One patient was well four months. One was unimproved at the expiration of six months. One patient, completely recovered from her cord symptoms, subsequently appeared with disseminated tuberculosis. One patient, well for nine months, developed a recurrence of his symptoms and died, in the author's opinion of a recurrence of the tumor.

Abstracts of the cases included in this study are appended in the following pages.

#### CASES OF HOUR-GLASS TUMORS OF THE CERVICAL REGION

Case 1.<sup>2</sup>—A man, aged 37, for nine months had weakness and stiffness in the left leg, then in the left arm, but without pain. Six months later, there developed a Brown-Séquard hemiparalysis corresponding to the sixth dorsal segment. Three

---

2. Bing and Bircher: *Deutsche Ztschr. f. Chir.*, 1909, vol. 98, quoted by Antoni.

months later, a disturbance in motion in the left upper arm and sensory changes to the level of the third rib were noted. Nine months after the beginning of the cord symptoms, a smooth tumor, the size of an egg and deeply situated, was found in the left supraclavicular triangle. The connection between this tumor and the tumor of the cord was not evident, and therefore it was decided to perform an exploratory operation. The tumor of the neck was easily surrounded and it was found that a process of the tumor, the size of a lead pencil, entered the intervertebral foramen between the fifth and sixth cervical vertebrae. The tumor of the neck was removed. Ten days later, a laminectomy was done and an extradural tumor found. The pathologic diagnosis was fibrosarcoma.

CASE 2.<sup>3</sup>—A girl, aged 16, had compression symptoms of the spinal cord, and at autopsy an extradural tumor the size of a walnut was found on the left side of the vertebral canal. This tumor had made, and lay, in a deep nest in the vertebra. It narrowed toward the dura and penetrated this membrane at the site of perforation of a nerve root. Within the dura, the tumor again enlarged to form an intradural tumor the size of a hazelnut. The tumor was firmly attached to the dura and deeply indented the cord. It lay at the level of the sixth cervical to the first dorsal segments. The cut surface of the tumor looked like that of the uterus. A nerve or nerves entered the tumor and disappeared within its substance. The pathologic diagnosis was not given, but the description suggests nerve cells and fibers indicating that the tumor had a neurogenic origin.

CASE 3.<sup>4</sup>—A woman, aged 31, began to have paralysis in the right leg and later, a spastic paralysis of both legs. Flaccid paralysis of the right arm developed, then of the left arm. There was paralysis of the bladder and rectum and anesthesia up to the third rib. The duration of illness was one year and eight months. Operation was refused. At autopsy, there was found a pure fibroma of the seventh cervical nerve, the size of a walnut, which was both intradural and extradural, and which extended outward through the intervertebral foramen to involve the brachial plexus. It was the opinion of the authors that the tumor arose extravertebrally because the larger portion of the tumor occupied this position. The pathologic diagnosis was fibroma.

CASE 4.<sup>5</sup>—A woman, aged 52, had been ill two years with compression symptoms of the cord. At autopsy, there was found just below the sixth cervical segment a tumor which in general was spindle shaped and 5.5 cm. long. Its greatest diameter was opposite the seventh cervical segment, the right root of which showed great thickening. The tumor was adherent to the pia and dura. It continued outward, and perforated the dura, and enlarged outside this membrane to form an extradural tumor. The site of perforation of the dura was presumably that of a nerve root. The intradural portion of the tumor had caused marked compression of the cord. The pathologic diagnosis was fibrosarcoma.

CASE 5.<sup>6</sup>—A boy, aged 14, had been ill a year with compression symptoms of the cord. At operation, a tumor of the neck was exposed; it was the size of a goose egg, with a thin connective tissue capsule, and apparently attached to the spinal accessory nerve. In the dissection, the nerve, however, was easily separated from the tumor. A branch of the brachial plexus required division because of its intimate connection with the tumor. After freeing the tumor, it was found that it possessed a finger-like process, which extended into the enlarged intervertebral

foramen between the fifth and sixth cervical vertebrae. In the removal of the tumor, this process was torn across. The remainder of the tumor within the intervertebral foramen, which is described as the size of a hazelnut, was removed without doing a laminectomy. The tumor then was apparently intraspinal but extradural. After operation, the symptoms of cord compression disappeared. Pathologically, the tumor was called a cellular fibroma.

CASE 6.<sup>7</sup>—A man, aged 26, had compression symptoms of the cord. At operation, a bilobed tumor was found, one portion intradural, the other extradural, lying about the level of the fifth cervical segment. The intradural portion of the tumor compressed the cord on the right, and was connected with the extradural portion by a narrowed segment, involving the nerve roots, one of which penetrated the intervertebral foramen and formed a large tumor of the lower-most cord of the right brachial plexus. There is no note that the extravertebral portion of the tumor was palpable in the neck, but from its size it should have been palpable. Pathologically, the tumor was called a fibroma.

CASE 7.<sup>8</sup>—A man died with compression symptoms of the cord. At autopsy, an extradural tumor was found, the narrowed portion of which passed through the intravertebral foramen between the second and third vertebrae, to be continuous with a freely movable tumor, the size of an orange, in the upper posterior triangle of the neck. From the description it would appear that there was also an intradural tumor, for the author stated that the tumor was quite distinct from the cord and that the arachnoid membrane could be readily separated from it. Pathologically, the tumor was called a fibroma.

CASE 8.<sup>9</sup>—A woman, aged 37, since her tenth year had a tumor at the right side of the neck behind the angle of the jaw; it grew slowly, was covered by the sternomastoid, and consisted of two or three nodular masses, well circumscribed and movable. A diagnosis of adenofibroma of the parotid was made. An operation was performed for extirpation of the tumor. It was found that upward the tumor narrowed and disappeared into the vertebral canal by a process the thickness of a finger, which penetrated through the intervertebral foramen between the second and third cervical vertebrae. On traction on this part of the tumor, a process 4 cm. long was drawn out of the intervertebral foramen. There was a sudden gush of cerebrospinal fluid, which led the operator to tie off the process, and abandon the operation. The patient recovered with perfect return of function. The author believed that the tumor arose from the dura.

CASE 9.<sup>10</sup>—A child, aged 9 months, showed at autopsy a tumor of the cervical spine which consisted of three distinct portions, all connected by a narrow bridge of tumor tissue. The extravertebral portion of the tumor was of considerable size and lay to the left of the lower cervical spine partly above and partly below the clavicle. This cervical tumor was connected with the intraspinal (extradural) portion of the tumor by a constricted bridge of tumor tissue which occupied the intravertebral foramen. The extradural tumor again was connected with an intradural tumor by a constricted part which passed through a nerve opening in the dura. The intradural tumor was larger than the extradural and markedly compressed the cord. The tumor was called a round cell sarcoma.

CASE 10.<sup>11</sup>—The details of the case are incomplete. A tumor was seen which presented in the neck and which extended through an intervertebral foramen into the vertebral canal involving and compressing the dura. There was marked compression of the cord. The opinion was that the tumor was a neurofibroma, which arose from a sensory nerve root and extended outward through an intervertebral foramen.

CASE 11.<sup>12</sup>—A boy, aged 9 years, had symptoms of a spinal hemiplegia for one year. On admission to the Marburg Hospital in June, 1913, the symptoms indicated compression of the sixth to the eighth cervical segments. There was dulness over the apex of the right lung. A roentgenogram showed a shadow in the right apical region interpreted as a sarcoma of the vertebra. At operation, an extrapleural mediastinal tumor was found which was removed at a second operation. At the same time, the lamina of the second dorsal vertebra was removed but no intraspinal tumor was found. At autopsy, an egg-shaped extradural tumor surrounded in part the lower cervical cord. Its lateral border was ragged and it was here that the extravertebral mediastinal portion of the tumor was broken off at the time of the second operation. The intraspinal tumor measured 5.7 by 2.5 by 2.5 cm. in diameter. Over its upper pole coursed the right fifth cervical nerve. The tumor partially surrounded the sixth to the eighth cervical segments as the symptoms indicated. Pathologic diagnosis was a neurofibroma arising from the spinal nerve. (The same case has been described by Erb.)

CASE 12.<sup>13</sup>—Briefly, the symptoms were as follows: There was neuralgia on the left side of the face for a number of years which was relieved by the extraction of some of the patient's teeth. In 1915, the patient noticed a small growth on the right side of the neck which slowly increased in size and was accompanied by pain in the back of the neck. Five years later, he was operated on for a tumor of the neck; the tumor was as large as a hen's egg and situated in the anterior triangle of the neck on the right. At operation, it was found to be located underneath the large vessels, was adherent to the deep muscles of the neck, and lay against the transverse processes of some of the cervical vertebrae. The tumor was encapsulated and at one spot seemed to extend into an intravertebral foramen. The pedicle extending into the foramen was ligated and cut, and the entire growth removed. The pathologic diagnosis was leiomyoma of branchiogenetic origin.

A few months before the operation for the removal of the cervical tumor, the patient began to suffer from pain in the back of the neck which radiated up into the head. Six months after the operation, he noticed that the right index finger was becoming weak, so that he could not move it as well as the other fingers. By August, 1921, he had little use of the right arm and diminished use of the right leg. There followed involvement of the left leg and the left upper arm. He was operated on at another hospital, in August, 1921, and a laminectomy in the lower cervical and upper thoracic region was performed. No tumor was found. The symptoms continued to advance until he was bedridden with almost complete loss of power in both upper and lower extremities. There was also incontinence of urine and feces. The examination will not be detailed. The symptoms were those of compression of the cord corresponding with the third cervical segment. The roentgenograms of the neck were negative.

13. Elsberg, Charles A.: Tumors of the Spinal Cord, New York, Paul B. Hoeber, 1925, case XL, p. 120.

On Jan. 17, 1922, the arches of the second, third and fourth and part of the fifth cervical vertebrae were removed. An incision of the dura exposed a well encapsulated tumor firmly adherent to the dura about 3 by 2 cm. in size at the level of the second cervical segment. This tumor had a projection which extended through the dura at the level of the intervertebral foramen between the second and third cervical vertebrae. There was no extradural tumor, however. The diagnosis was leiomyoma, and a comparison of this tumor was made with the tumor removed from the neck, showing an identical pathologic picture. The patient recovered, and finally became practically well.

CASE 13.<sup>14</sup>—A girl, aged 12, one year before admission to the hospital, first noticed that the right leg was weaker than the left. At the same time she had some pain in the right shoulder and inner side of the right thigh. After three months the left lower and the right upper extremity began to grow weaker. A few months before entrance to the hospital the strength of the left arm also became less. There were steady advances in all symptoms. Frequent involuntary twitching of the legs developed. The patient had been bedridden for several months. Examination showed diminution in the power of both upper extremities, more marked on the right, spastic paraplegia, and sensory disturbances. The roentgen examination showed a localized loss of substance of the arches of the fourth, fifth and sixth cervical vertebrae.

On May 31, 1912, laminectomy was performed. A large well encapsulated extradural tumor was found to the right and in front of the dural sac. There was a large cavity in the arches of the fourth, fifth and sixth cervical vertebrae from bone absorption. Some oozing from the cavity was controlled by bone wax. The patient recovered and improved very rapidly. Three months after operation she was walking without assistance, and the power in the upper extremities almost completely returned. She returned to the hospital one year later with recurrence of symptoms. A second operation on Oct. 17, 1913, showed an encapsulated extradural mass, which, on removal, proved to be a small mass of wax with what was supposed to be tumor tissue around it. Microscopic examination, however, failed to show any evidence of tumor. The patient again recovered, and in 1921, eight years after the second operation, a letter from Dr. Emmett Rixford, of San Francisco, stated that for one year the patient had had increasing signs of spinal compression at the seventh cervical level. In addition, there was a large round tumor on the right side of the neck beneath the sternomastoid muscle. At operation, performed by Rixford about nine years after the second operation, an encapsulated tumor the size of a fairly large lemon was removed from beneath the blood vessels. It possessed a pedicle which was about 2 cm. in diameter and which passed into the spinal canal through the intervertebral foramen between the fifth and sixth cervical vertebrae. Following this operation, the patient was again able to walk and was much improved.

The pathologic diagnosis was fibrosarcoma.

CASE 14.<sup>15</sup>—Elsberg referred to and gave illustrations of a child who had paralysis of all four extremities and who presented a visible and palpable tumor in the left posterior triangle of the neck (figs. 11 and 2). Roentgen examination showed partial destruction of the fifth cervical vertebra. At operation there was found an extradural tumor which markedly compressed the cervical cord and which was continuous by a constricted portion through the intravertebral foramen with a large tumor of the posterior triangle of the neck. The tumor was completely

14. Elsberg (footnote 13, case LV, p. 165).

15. Elsberg (footnote 13, pp. 331 and 348).

and satisfactorily removed. The diagnosis was neurofibroma. Elsberg remarked that Flateau and Sawicki proposed the name of "cervical-neurofibroma" for dumb-bell shaped tumors that originate from nerve roots, one part lying within the spinal canal and the other part forming a tumor at the root of the neck.

CASE 15.<sup>16</sup>—The patient died, and postmortem examination showed an extradural tumor which was continuous, by two enlarged nerve roots passing through adjoining intravertebral foramina, with a large tumor occupying the region of the neck above the clavicle. The autopsy showed that this tumor could have been completely extirpated if the patient had been subjected to operative intervention (figs. 3 and 4). The tumor was called a neurofibroma.

CASE 16.<sup>17</sup>—A girl, aged 14, presented a characteristic Brown-Séquard syndrome. At operation, a tumor, considered congenital, was found filling the body of the sixth cervical vertebra. The tumor pierced the bony shell posteriorly and perforated the spinal dura laterally, where it flared out into an intradural tumor which compressed the cord. Nothing definite is stated regarding an extravertebral

Fig. 11.—Photograph of patient with a cervical hour-glass tumor showing a tumor of the left side of the neck; the operative observations are shown in figure 2 (Elsberg).

portion of this tumor, but the illustration which accompanies the case report suggests this (fig. 12). The tumor was considered congenital but its exact nature is not stated.

CASE 17.<sup>18</sup>—A woman, aged 37, presented symptoms of cord compression. Laminectomy was performed in the region of the second and third cervical vertebrae. On the anterior surface of the cord between the dura and the bone there was a grayish-red, very soft tumor, which was incompletely removed. The dura was opened, but there is no note as to an intradural tumor. Death occurred ten hours after operation. At autopsy there was found a paravertebral tumor, oval.

18. Hildebrand: *Arch. f. klin. Chir.* **94**: 203, 1911; cited by Guleke.

the size of a walnut, very soft and gelatinous, lying between the second and the third cervical vertebrae. This paravertebral tumor connected with the tumor in the spinal canal, through the intervertebral foramen between the second and third cervical vertebrae. Microscopically, the tumor was a mixed cell sarcoma, with myxomatous degeneration.

CASE 18.<sup>11</sup>—In a patient, aged 40, a tumor diagnosed as a neurinoma, the size of a hen's egg, lay on the right side of the neck, fairly high up. A process of the tumor, the thickness of a finger, followed the nerve through an intervertebral foramen. This was left behind at the time of the first operation and two months later caused compression symptoms of the cervical cord. A second operation, with a laminectomy, showed an extradural tumor at the level of the atlas. This tumor was removed, with disappearance of the compression symptoms.

Fig. 12.—Hour-glass tumor of the cervical region; observations at operation; case 16 under Tumors of Cervical Region (Dandy).

#### CASES OF HOUR-GLASS TUMORS OF THE DORSAL REGION

CASE 1.<sup>20</sup>—A man, aged 43, in August, 1917, noticed a feeling of heat in the right foot. Later there occurred sticking and crawling paresthesias in the right foot, extending up to the right hip. These sensations spread to the right half of the abdomen and back. In the spring of 1918, he began to have weakness of the left leg and loss of sensation. Later, he had difficulty in walking. On examination, Oct. 10, 1918, there was marked spastic paralysis of the left leg and loss of sensation below a line 3 cm. above the umbilicus. There was no paralysis of the bladder or rectum. Two months later, there was paralysis also of the right leg

19. Naegeli, cited by Coenen: *Deutsche Ztschr. f. Chir.* **203**: 71, 1927.

20. Antoni, N. R. E.: *Ueber Rückenmarkstumoren und Neurofibrome*, München, J. F. Bergmann, 1920.

and weakness of the bladder and rectum. The roentgenogram of the spine showed the disappearance of the intervertebral disk between the eighth and ninth dorsal vertebrae. The eighth dorsal vertebra appeared compressed. At this level there was a lesion the size of a nut where the bone of the vertebra appeared to be completely absent. Laminectomy was performed on Aug. 8, 1919, with removal of the seventh to ninth dorsal arches. Corresponding with the eighth thoracic was an extradural tumor the size of a nut. This was attached to the dura but could be freed from the surrounding structures. The dura was opened and it was then found that the extradural tumor was only one part of the growth, and that a tumor of equal size was intradural. The intradural tumor extended along the left dorsolateral part of the cord a distance of 3 cm. The two portions of the tumor were connected by a narrow bridge of tumor tissue. The extradural portion of the tumor had herniated the dura outward so that the dura formed a sac around it. The patient recovered after the removal of the tumor. There was improvement in sensation one month later but no other change was noted. The pathologic diagnosis was neurinoma.

CASE 2.<sup>21</sup>—A boy, aged 11 years, since the fall of 1912, had had pain in the back radiating around to the abdomen. A physician made a diagnosis of floating kidney and operated for this condition. The pain was unaffected, and while still in the hospital recovering from this operation, the boy developed weakness and then paralysis of both legs, beginning on the right. In March, 1913, he left the hospital completely paralyzed. A few weeks later he came under Guleke's care. Examination showed a flaccid paralysis of both legs. There was a slight kyphosis in the region extending from the eleventh dorsal to the second lumbar spine. In this region the spine was rigid and tender. There were marked sensory disturbances over the legs up to the level of the iliac crest. Lumbar puncture showed no increase in pressure. The fluid was slightly yellowish. There was an increase in albumin and a few mononuclear cells. Operation was performed and the laminae of the eleventh dorsal to the second lumbar vertebra, inclusive, removed. The dura did not appear under tension. It was opened and nothing found at this level. The vertebral canal was probed cranialward and an obstruction found. The laminae of the sixth, seventh and eighth dorsal vertebrae were then removed. At the level of the seventh dorsal there was an extradural tumor 4.5 cm. long, hard, yellowish, and encapsulated. Cord compression to the left was noted. The tumor was adherent to the dura but could be separated from this membrane. From this tumor there proceeded a narrow pedicle of tumor tissue which passed out of the canal through the intervertebral foramen between the seventh and eighth dorsal vertebrae. The foramen was much enlarged. Paravertebrally, the tumor enlarged again and divided into two portions, one of which extended into the muscles of the back, while the other proceeded between the heads of corresponding ribs into the posterior mediastinum. The entire tumor was removed. The patient recovered from the operation but developed a cerebrospinal fistula which became infected after three weeks and gave rise to a meningitis with death. The pathologic diagnosis was large cell sarcoma.

CASE 3.<sup>21</sup>—A youth, aged 21, seven years previous to admission had a sudden pain in his back following the lifting of a sack of meal. For eight days there was severe pain which had since recurred. In September, 1912, he began to have stiffness in the left leg. About the same time he had pain in the abdomen in the region of the stomach. In December stiffness also appeared in the right leg. The man came to the clinic because of the supposed stomach trouble. Examina-

tion showed weakness and uncertainty in gait with dragging of the left foot. On the back to the left of the sixth to the ninth dorsal spines was a palpable tumor the size of an egg, ovoid in shape, smooth, not movable, hard, elastic and apparently lying in the muscles. The skin over the tumor was normal. There was no visible or palpable deformity of the spine. Roentgen examination failed to show anything definite, but a suggestive shadow in the left posterior mediastinum the size of a peach was present and at the same level as the tumor of the back. There was a marked spasticity of the legs and anesthesia over the legs and upward to the sixth dorsal on the right and the eighth on the left. There was no disturbance of the bladder and rectum. At operation, a curved incision was made over the fourth to the eleventh vertebrae with the dissection of a skin flap. The superficial tumor already described was surrounded and followed deeply to a pedicle which was cut across and the external tumor removed. It was then seen that the pedicle entered the intervertebral foramen between the eighth and ninth dorsal vertebrae. The laminae of the sixth to the ninth dorsal vertebrae were then removed, and it was found that a large extradural tumor occupied the vertebral canal from the sixth to the ninth dorsal laminae and markedly compressed the cord. The tumor was hard, nodular, fibrous and identical with the tumor of the back. The tumor was separated from the dura and removed. After removal of this tumor it was apparent that the tumor also penetrated the intervertebral foramen between the seventh and eighth dorsal vertebrae and extended into the posterior mediastinum. The transverse and articular processes of the seventh and eighth dorsal vertebrae together with the head and neck of the corresponding ribs were removed. Through the opening thus obtained a tumor the size of a lemon was seen lying in the posterior mediastinum near the aorta which had pushed forward the anterior longitudinal ligament of the vertebra as a capsule. This tumor was also removed without injury to the pleura. Recovery was uneventful with return of function. Three years after operation, the patient was practically well, although there remained some weakness of the legs. The pathologic diagnosis was *fibrosarcoma*.

CASE 4.<sup>22</sup>—A woman, aged 33, for many years had a diffuse fibrolipomatosis over the whole body and an extensive pigmented nevus over the right shoulder. Since the middle of April, 1921, the patient had had a feeling of weight and numbness of both legs, more marked in the left. By the end of April there was marked impairment in walking. Marked pain appeared in both legs which was thought to be sciatica. Eventually, there was paralysis of the bladder. The rectal sphincters remained unaffected. On examination, the spastic paralysis of both legs was evident. The reflexes were exaggerated. There were sensory disturbances over the legs extending upward in front about three fingerbreadths below the nipple and behind to the level of the eleventh thoracic spine. The ninth and tenth spines were prominent and kyphotic but not tender on pressure. The spine was freely movable. Roentgen examination failed to show any lesion of the spine but did show an oval shadow the size of a plum in the left mediastinum about the level of the fifth dorsal vertebra. At operation, the third to the eighth dorsal laminae were resected. There was exposed at the upper portion of the sixth lamina the lower pole of a grayish, white, hard, circumscribed tumor 3.5 by 1.5 cm. in diameter impinging on the dura. Examination of this extradural tumor showed that a process of tumor proceeded outward through the intervertebral foramen between the fifth and sixth dorsal vertebrae on the left. Beyond the foramen the tumor again enlarged and projected into the deep muscles of the back (fig. 7). This paravertebral portion of the growth was made up of several nodules; however, all were connected. After

---

22. Guleke: *Arch. f. klin. Chir.* **119**: 833, 1922.

mobilization of the intraspinal and paravertebral portions of the tumor, it was found that the tumor sent off another process which penetrated the intervertebral foramen between the fourth and fifth dorsal vertebrae and projected into the left posterior mediastinum (fig. 1). The removal of this portion of the tumor required the resection of the transverse processes of the fourth and fifth dorsal vertebrae and 4 cm. of the corresponding ribs. The mediastinal tumor on removal measured 3.5 by 5.5 cm. in diameter. In the course of its removal, the pleura was torn and the operation was continued under positive pressure anesthesia. Also, in the removal of this portion of the tumor there was found still another tumor the size of a hazelnut which had made a nest for itself in the body of the fifth dorsal vertebra (fig. 9). Following operation the patient developed a hemopneumothorax and then an empyema which required rib resection and drainage. The patient died ten days later of sepsis. At autopsy it was found that a meningitis had followed the empyema. There were no more tumors found. The pathologic diagnosis was fibrosarcoma. The author thought that the tumor arose from the inner periosteum of the vertebral canal.

CASE 5.<sup>23</sup>—A woman, aged 33, for five years had a drawing sensation in the right side of the chest, and difficulty in lying on that side. No cough or elevation in temperature were noted until March, 1923, when the patient developed a cold with cough and dyspnea. This persisted for three weeks, but did not entirely clear up. Because of indefinite pulmonary symptoms, her physician sent her to a roentgenologist who found in the field of the right lung posteriorly a shadow the size of an infant's head which was sharply defined laterally but mesially fused with the shadow of the mediastinum. This intrathoracic tumor was thought to be an echinococcus cyst. Further examination by the author showed that the tumor extended from the fourth to the tenth rib on the right side and laterally to within two fingerbreadths of the thoracic wall (fig. 5). There was no fluid in the chest nor disturbance in the movements of the diaphragm. There were no symptoms with reference to the spinal cord. Operation was performed on July 16, 1923, with resection of the eighth, ninth and tenth ribs over a distance of from 8 to 10 cm. There appeared under the pleura a yellowish solid tumor which moved slightly with respiration. The two leaves of the pleura were sutured together over the extent of the operative field. Tincture of iodine was applied to the pleura. This constituted the first stage of the operation. At the second stage, a month later, the wound was reopened and the tumor punctured through the pleura with an aspirating needle. At a depth of from 3 to 4 cm. a small amount of slightly bloody serous fluid was aspirated. An incision was made in the pleura and into the capsule of the tumor. There followed an extrusion of a yellowish-white tumor tissue. A finger was then inserted between the surface of the tumor and this capsule and the tumor bluntly freed from it. Further laterally, however, the thin capsule tore and the pleura was freely opened. The operation was continued under positive pressure. Finally the whole tumor was surrounded and it was found that it narrowed posteriorly to a pedicle. This pedicle, not much larger than a lead pencil, disappeared into an intervertebral foramen and was apparently the only point of attachment of the tumor. By traction on the tumor this pedicle was pulled out of the intervertebral foramen. There was very little bleeding. The wound was closed without drainage under strong positive pressure. Following the operation, the patient developed a pleural exudate and then an empyema which required rib resection and drainage. She was finally discharged from the hospital apparently well. She was seen four months after operation and was in good condition. On

section of the tumor there was found in its center a cystic cavity measuring 16 by 8 cm. in diameter (fig. 6). The pathologic diagnosis was neurinoma.

CASE 6.<sup>21</sup>—A woman, aged 51, at autopsy showed a tumor which was intradural, the size of a large marble and adherent to the dura on the right side. Connected with this tumor by a narrow pedicle which extended through the dura was a second extradural tumor which was slightly smaller, softer, and surrounded some nerve filaments taken to be the eleventh dorsal pair. There was no note of a paravertebral extension of the tumor. The tumor was called a fibrosarcoma.

CASE 7.<sup>25</sup>—A girl, aged 19, at autopsy showed a tumor 3 by 2 cm. in diameter between the anterior and posterior roots of the ninth and tenth dorsal nerves behind the dentate ligament. The tenth anterior root was embedded and lost in the tumor. The intradural tumor narrowed to an isthmus which penetrated the dura and enlarged again to form an extradural tumor. The extradural tumor divided into two parts, one of which followed or corresponded with the intercostal nerve; the other followed or corresponded with the dorsal ramus of the segmental nerve. The intradural tumor was smooth; the extradural, lobular. The pathologic diagnosis was that of a neuroma arising from the ninth dorsal nerve with an extradural prolongation.

CASE 8.<sup>26</sup>—A man, aged 35, entered the hospital with complete paraplegia. For seven or eight years he suffered with violent pain in the region of the liver which extended around the body to the right as far as the spine. In 1915, he began to have weakness of the legs, especially of the right. This had progressed to complete paraplegia. Examination showed paraplegia of the lower extremities with exaggerated reflexes. Sensory disturbances were present over the lower extremities extending upward to the level of the seventh dorsal segment. Roentgen examination of the spine failed to show any lesion of the spine itself but did show a shadow in the right pulmonary field between the fifth and seventh ribs. This apparent intrathoracic tumor corresponded in its level with the evident lesion of the cord. Laminectomy was performed by Professor Roux. There presented an extradural tumor, ovoid in shape, about the size of a large cherry, with an isthmus which passed out through the intervertebral foramen. This isthmus apparently communicated with the mediastinal tumor. The extradural tumor with a part of its pedicle was removed. The mediastinal tumor was not removed. Following operation, the patient recovered motion and sensation, and the end-result was very satisfactory. The pathologic diagnosis was small cell sarcoma. The late result was not given.

CASE 9.<sup>27</sup>—One of several cases of intrathoracic tumor studied by Banse was that of a man, aged 32, who at autopsy showed a "pleural neurofibroma" which narrowed to a pedicle. This pedicle extended through the intervertebral foramen into the intraspinal space and caused compression symptoms of the cord. There were tumor nodules in the portal vein and in the spleen. The case was considered one of primary thoracic or mediastinal tumor which had extended into the spinal canal.

CASE 10.<sup>28</sup>—A man, aged 19, presented compression symptoms of the cord. At operation, a tumor was found at the level of the first dorsal segment. One portion

27. Banse: *Inaug. Diss.*, Greifswald, 1908.

28. Starr: *M. Rec.* **82**: 458, 1912.

of this tumor was intradural, was attached to the dura and compressed the cord. It extended through the dura where it enlarged to form an extradural pear-shaped tumor, and terminated in a nerve. It was necessary to divide the first dorsal nerve in order to remove the tumor. The tumor was encapsulated, hard, and was considered pathologically to be a fibroma.

CASE 11.<sup>29</sup>—The age and sex of the patient are not given. The symptoms were those of cord compression corresponding to the fifth and sixth dorsal segments. The diagnosis of intraspinal tumor was made. A roentgenogram taken later showed a tumor shadow lying in front of and to the right of the vertebrae in the posterior mediastinum. At operation, an intraspinal but extradural tumor was found compressing the cord about the fifth to the sixth dorsal segments. This tumor narrowed to a pedicle which had extended through an intervertebral foramen and was continuous with a much larger tumor which occupied the posterior mediastinum. The tumor was removed. The result of the operation was not stated. The tumor was called a neurofibroma.

CASE 12.<sup>30</sup>—A paralytic child, born in June, 1909, presented a paravertebral swelling in the back which proved on exploration, in 1911, to be a malignant tumor (spindle cell sarcoma). Under Coley's toxin treatment, the growth disappeared but the paraplegia persisted. A laminectomy ten years later (1921) disclosed an intraspinal but extradural tumor which proved to be a ganglioneuroma. In February, 1911, following an injury there was progressive weakness of the legs associated with a paravertebral swelling opposite the middle of the scapula on the right side. This tumor increased in size and was associated with a progressive weakness of the extremities. The tumor of the back was explored and was found to be well defined, and apparently arising from the laminae or the right transverse process of the sixth dorsal vertebra. The condition was thought to be inoperable. Sections removed at that time were diagnosed as a fibrosarcoma. Under Coley's toxin treatment, the tumor disappeared. Within eight months it was entirely gone, and for the following eight years there was no return of this swelling. The child came under Cushing's care ten years after the first operation with the paraplegia still present. No evidence of the previous tumor of the back was found. Roentgenograms of the spine showed a cloudy area at the site of this lesion. No detailed report was made concerning the possibility of a tumor of the mediastinum. At operation, an extradural tumor was found encircling the cord. It communicated with the relic of the original tumor of the back through an enlarged intervertebral foramen. On the right of the laminae a dense, scarlike tissue was found in the spinal muscles which proved to be the residuum of the original tumor. No note was made of any tumor in the posterior mediastinum. Recovery followed the operation. Five years later, the boy was improved. Pathologically, the tumor was considered a benign ganglioneuroma transformed into such from a malignant sympathicoblastoma.

CASE 13.<sup>31</sup>—A woman, aged 48, for ten years had pain in the right side of the back just below the scapula. The pain was burning, did not radiate and was more severe at night. There were no symptoms of compression of the cord. On examination, there was a definite point of tenderness to the right of the spine at about the level of the fifth thoracic vertebra. The deep reflexes were exaggerated. Fluoroscopic examination of the chest showed a well rounded shadow projecting from the mediastinum toward the right side at the level of the second interspace

29. Mager: *Wein. klin. Wchnschr.* **25**: 900, 1912.

30. Cushing and Wolbach: *Am. J. Path.* **3**: 203, 1927.

31. Cushing: Personal communication to the author.

anteriorly and at the level of the sixth and seventh ribs posteriorly. The x-ray films confirmed the fluoroscopic observations. There was slight angulation of the dorsal vertebrae at the level of the shadow of the tumor. Operation was performed in two stages with the approach to the mediastinal tumor from behind. A solid, firmly fixed, sessile tumor, the size of a golf ball, was found fixed to the side of the vertebral column and with two or three smaller nodules which nestled in between the two ribs. These had caused pressure absorption of the vertebrae against which they lay. The tumor was broken off from its attachment to the spine. From the notes on the case it was not positively determined that a portion of the tumor entered the intervertebral foramen, but judging from similar cases in the literature this is probable. The patient recovered with complete disappearance of the pain. Five years later it is noted that she again had pain on her right side, somewhat lower than that she had before operation. There was also pain in the lower part of the back when she vomited. A roentgenogram of the spine showed marked scoliosis in the upper dorsal spine. The patient was killed in an automobile accident five years after the operation.

CASE 14.<sup>32</sup>—A man, aged 38, had paraplegia of the lower extremities for two and one half years. There were no intrathoracic symptoms. A single anteroposterior x-ray plate of the spine showed no abnormalities. There was complete paraplegia of the lower extremities and anesthesia which extended upward to the level of the eighth dorsal vertebra behind and to the xiphoid in front. At operation, an intraspinal but extradural tumor was found at the level of the sixth thoracic lamina lying to the left side and partially destroying the laminae and the vertebrae against which it lay. The tumor narrowed laterally and passed out through an enlarged intervertebral foramen into the posterior mediastinum (fig. 13). The removal of the mediastinal portion of the tumor was somewhat difficult because of the suction present. It was removed, however, without opening the pleura. One spinal nerve passed into the growth and this nerve had to be sectioned in order to remove it. Pathologically, the tumor was considered a neurofibroma. The patient recovered and twelve years later was entirely well.

CASE 15.<sup>32</sup>—A white woman, aged 48, entered the Cincinnati General Hospital complaining of neuritis between the shoulder blades. For a year she had what she called rheumatism in the right leg and severe girdling pains around the upper part of the thorax, sometimes accompanied by smothering spells. There was progressive weakness of the legs which rather suddenly terminated in complete paralysis. Examination showed a paralysis of both legs, flaccid rather than spastic in type. Deep reflexes were present but not active. There was loss of sensation over the lower extremities and extending upward almost to the suprasternal notch in front and the first thoracic vertebra behind. Examination of the chest showed an area of dulness over the left upper side of the chest both in front and behind. A roentgenogram of the chest showed a large tumor shadow in the upper half of the left lung field with partial destruction of the first and second thoracic vertebra and corresponding ribs near the spine (fig. 14).

This patient was for a time on another service and was eventually seen by me in consultation. At that time her condition was such as to preclude any operative intervention. The patient died. An autopsy could not be obtained; therefore, the observations were not verified. A possibility that the spinal lesion was a metastasis rather than a direct growth from the thoracic tumor cannot be denied, but this case strongly suggests an hour-glass form of tumor.

---

32. Heuer: Cases 14 and 15 have not been published previously.

CASE 16.<sup>33</sup>—A boy, aged 3 years, thirteen months before admission to the hospital complained of abdominal cramps. The parents noticed that the lower legs were weak and shook spasmodically. A roentgen examination of the chest at this time showed a small tumor mass in the upper posterior mediastinum. Two months later the child began to drag the right leg, and soon afterward the left leg. A few weeks later, paralysis developed. Frequent roentgen examinations during the year failed to show any appreciable increase in the mediastinal growth. Roentgenograms of the spine failed to show any abnormalities in the vertebrae. At operation, the laminae of the seventh cervical and upper fifth dorsal vertebrae were removed. Underneath the first to the fifth thoracic laminae was a large, extradural tumor, which lay more on the left than the right side, projections from which extended into the intervertebral foramen. The entire intraspinal mass was removed in one piece. Apparently, no attempt was made to remove the mediastinal portion of the tumor. Death occurred twenty-eight hours after operation. The pathologic diagnosis was giant cell sarcoma. Elsberg stated, however, that the true

Fig. 13.—Hour-glass tumor involving the spinal cord and mediastinum; operative removal; personal observation; case 14 under Tumors of Dorsal Region.

nature of the tumor was, in his opinion, not established, and it suggested to him a ganglioneuroma. However, no medullated or nonmedullated nerve fibers were found in the tumor by specific staining methods.

CASE 17.<sup>34</sup>—A man, aged 54, had symptoms of cord compression of six months' duration. Examination showed a spastic paresis with moderate diminution in sensation below the level of the sixth thoracic segment. The roentgenogram showed an irregular oval shadow in the posterior mediastinum to the left of the third, fourth and fifth thoracic vertebrae, and extending outward for 4 or 5 cm. from the median line (fig. 15). At operation, an extradural tumor 4 by 2 cm. in size was found which had produced a nest for itself in the bodies of the vertebrae. The dura in contact with the tumor was thickened and seemed to be invaded by the growth. An isthmus of the tumor passed out through the intervertebral foramen between the fifth and sixth thoracic vertebrae, and enlarged to form a tumor of the posterior mediastinum. The patient recovered, but without improvement in his

33. Elsberg (footnote 13, case LVIII, p. 175).

34. Elsberg (footnote 13, case LXVII, p. 198).

Fig. 14.—Roentgenogram of patient with cord compression showing a large intrathoracic tumor (personal observation); case 15 under Tumors of Dorsal Region.

Fig. 15.—Roentgenogram of thorax of patient with symptoms of cord compression showing a tumor shadow in the posterior mediastinum; case 17 under Tumors of Dorsal Region (Elsberg).

symptoms. The tumor was called an extradural psammoma, but the author noted that while one part of the tumor contains numerous psammoma bodies other parts of the growth contain cells very similar to sympathetic ganglion cells. In the absence of medullated or nonmedullated nerve fibers, the diagnosis of ganglioma did not seem justified.

CASE 18.<sup>35</sup>—Elsberg referred to a chondrosarcoma arising from the vertebrae which caused compression symptoms of the cord. The roentgenogram showed a tumor projecting outward from the thoracic spine opposite the eleventh and twelfth dorsal vertebrae (fig. 16). The details of the case are lacking. The case suggests very much an hour-glass tumor arising primarily from the spine and entering the spinal canal.

Fig. 16.—Roentgenogram of the thorax of a patient with cord compression showing a chondrosarcoma of the vertebrae; case 18 under Tumors of the Dorsal Region (Elsberg).

CASES 19, 20, 21 and 22.<sup>37</sup>—Dandy briefly referred to four extradural neuromas which had caused compression symptoms of the cord. At operation, they were all found to have a dumb-bell shape. The extradural portion of the tumor narrowed and passed out through an intervertebral foramen, where it enlarged again to form a paravertebral tumor which extended to or into the posterior mediastinum. It seemed probable to the author that the point of origin of these tumors was at the point of constriction within the intervertebral foramen and probably from the ganglions. Into each tumor a sensory and motor nerve was traced, but the nerves were lost in the tumor. In two of the four cases the sections of the tumors showed large numbers of giant cells so as to suggest the histologic diagnosis of giant cell sarcoma (figs. 17 and 18).

35. Elsberg: *Ann Surg.* **81**:1057, 1925; footnote 13

CASE 23.<sup>17</sup>—A girl, aged 19, for five years had a rather rapidly developing paraplegia and loss of sphincter control. The roentgenogram showed the shadow of a large, intrathoracic tumor of which, according to the author, the intraspinal growth was a prolongation, and which had entered the spinal canal and caused compression of the cord. The intrathoracic tumor was explored by Finney and was found to be very vascular with expansile pulsation, and was considered to be inoperable. A piece of tissue was removed for diagnosis, but unfortunately was lost. The presumptive diagnosis was angiosarcoma. The patient was given radium treatments, and the paralysis of the extremities quickly disappeared. She has been

Fig. 17.—Diagrammatic representation of location and manner of growth of extradural neuromas as seen by Dandy; cases 19 to 22 under Tumors of Dorsal Region.

well for five years. Despite the disappearance of the spinal cord symptoms, the intrathoracic tumor has been unaffected as shown by repeated roentgenograms of the chest. The intrathoracic tumor, however, has never given rise to symptoms.

CASE 24.<sup>36</sup>—A man, aged 51, for eight years had had pain in his right side. An exploratory laparotomy with removal of the appendix was followed by relief of pain for a time, but it later returned. There appeared a gradual progressive paraplegia with sensory disturbance corresponding to the tenth dorsal segment.

36. Borchardt: *Klin Wchnschr.* 5:636, 1926.

Roentgen observations are not recorded. At operation, an extradural tumor the size of a plum was found at the level of the fifth dorsal vertebra. The tumor narrowed to an isthmus which extended outward through the intervertebral foramen of the fifth and sixth dorsal vertebrae. This isthmus was continuous with a second larger tumor in the posterior mediastinum. Both the intraspinal and mediastinal tumors were removed. There was prompt recovery with disappearance of the paraplegia. The tumor had one nerve attached to it which was sectioned in the course of the removal of the tumor. The diagnosis was neurinoma.

CASE 25.<sup>30</sup>—A man, aged 57, following an attack of grip a year before examination, began to have pain in the abdomen and back, then a heavy and dull sensation in the legs followed by weakness. Eventually, he was unable to walk. Examination showed paraplegia of the legs with loss of sensation up to the rib margin. Roentgen examination showed rarefaction in the bodies of the fourth to the sixth dorsal vertebrae. The injection of iodized oil 40 per cent showed an arrest of the material at the fourth dorsal. At operation, an extradural tumor was found at the level of the fifth and sixth dorsal laminae. It was the size of a plum and soft like

Fig. 18.—Specimen of hour-glass tumor (extradural neuroma) removed by Dandy; cases 19 to 22 under Tumors of Dorsal Region.

a sarcoma. A process of the tumor entered the intervertebral foramen beyond which it enlarged again to form a mediastinal tumor. Both tumors were removed with an attached nerve. The patient recovered from the operation. Four weeks later there was a lighting up of an old bronchiectatic abscess with pneumonia. The patient died. The pathologic diagnosis was neurinoma.

CASE 26.<sup>30</sup>—A man, aged 30, had had pigmentation of the body since childhood. In January, 1924, he complained of weakness in the legs, and by March was bedridden. Examination showed the skin of the back and extremities to be covered with pigmented areas and skin tumors. Over the acromial end of the clavicle there was a large, brownish, pigmented, lobulated tumor. Roentgen examination of the chest showed a tumor shadow in the left apical region. Injection of iodized oil 40 per cent intradurally was arrested at the seventh cervical vertebra. At operation, there was found at the level of the sixth and seventh cervical and the first dorsal vertebrae an intradural tumor firmly fixed to the dura. It continued through the dura and through the intervertebral foramen into the posterior mediastinum. The intraspinal portion of the tumor was removed, but the mediastinal portion was not. The patient died following the operation. Autopsy showed a large

tumor in the left apical region (fig. 8). There was also found a diffuse thickening of the nerves of the brachial plexus. The condition, therefore, was one of tumor in association with von Recklinghausen's disease. The diagnosis of the intraspinal tumor was neurofibroma.

CASE 27.<sup>37</sup>—A woman, aged 35, was brought into the hospital unconscious, and died before a history was obtained. No account of a physical examination was recorded. At autopsy, a tumor mass was found in the posterior mediastinum, closely adherent to the bodies of the second and third thoracic vertebrae. It projected into the left thoracic cavity, but was covered by the pleura. A process of this tumor extended into the spinal canal through the intervertebral foramen. Its connection with the sympathetic was not noted. When cut, the surface of the tumor looked like that of a uterus. According to Stout, this is the first ganglioneuroma reported in the literature.

CASE 28.<sup>38</sup>—A boy, aged 2½ years, was well until seven months before coming under observation, when he began to have pain in the stomach. Three months later, he became unsteady on his feet and began to drag the right foot. Sometime thereafter, he was practically paralyzed with loss of control of the bladder and rectum. Examination showed marked dullness over the left upper lobe of the lung, front and back, with sibilant and sonorous râles and bronchial breathing. The roentgenogram of the chest showed a dense shadow over the upper portion of the left lung interpreted as a new growth. The cervical vertebrae were fixed and rigid; there was a marked anterior curvature of the thoracic vertebrae. Marked weakness of both legs was noted. The reflexes were present and active. There was ankle clonus on both sides. Sensations seemed diminished. Four days after admission to the hospital a needle was introduced in the third left interspace in the anterior axillary line. No fluid was obtained, but a piece of tissue remained in the lumen of the needle. On examination, this tissue showed ganglion cells and neurofibrils. The nature of the growth, however, was not recognized until two years later. The condition was considered inoperable and the patient released. Seven months later the child was operated on at the Neurological Institute by Elsberg in an attempt to relieve pressure on the thoracic cord which had become progressively more marked. An extradural tumor was found in the spinal canal occupying the upper dorsal region which was continuous with the tumor in the chest by a pedicle of tumor tissue which had extended into an intervertebral foramen. The child died shortly after operation. No autopsy was obtained. The pathologic diagnosis was ganglioneuroma.

CASE 29.<sup>39</sup>—This case is incompletely reported. There was a tumor arising from the seventh rib near the spine which lay in the posterior mediastinum. A process of the tumor entered the intervertebral foramen and caused compression symptoms of the cord. The tumor was a chondroma.

CASE 30.<sup>40</sup>—The tumor originated from the head of the rib, and lay in the posterior mediastinum. A process of the tumor entered the intervertebral foramen and caused compression symptoms of the cord.

CASE 31.<sup>41</sup>—A woman, aged 20, with paralysis of the legs, presented a tumor mass just to the right of the twelfth thoracic vertebra which had been present for

40. Paget: This case is also cited by Nigst and is similar to Barth's case.

41. Carman and Davis: *Radiology* **3**:185, 1924.

two years, and which had grown to 6 cm. in diameter. There was a spastic paralysis of the legs and sensory disturbances. At operation, the tumor of the back was completely removed and was found not to be connected with the vertebral column. It was diagnosed as a fibroma. At a second operation one month later, a laminectomy was done and a tumor found, extradural in location, which had eroded the arches of the eleventh and twelfth dorsal vertebrae. It had grown outward between the arches and extended into the muscles of the back. This tumor also was called a fibroma. The roentgenogram in this case showed a picture resembling a trabeculated cyst (fig. 19).

CASE 32.<sup>19</sup>—A woman, aged 44, presented a tumor the size of a plum in the muscles of the back at the level of the sixth and seventh dorsal vertebrae. This tumor was continuous through the intervertebral foramen, with an extradural tumor, 4 cm. in length, which compressed the cord. There was no note made of a mediastinal tumor in this case. The tumor was called a neurinoma or neurofibroma.

Fig. 19.—Roentgenogram of spine in a case of hour-glass tumor of the dorsal region giving the appearance of a trabeculated cyst; case 31 under *Tumors of the Dorsal Region* (Carman and Davis).

CASE 33.<sup>42</sup>—A boy, aged 4 years, had paralysis of the legs, bladder and rectum. At operation there was a ganglioneuroma the size of a goose egg to the left of the spine in the region of the eighth to the twelfth dorsal vertebrae, which was continuous with a tumor of the loin and pelvis. Although a considerable portion of the tumor was left behind under the lower ribs, the paralysis from which the boy suffered improved, and there was even relief from the pressure on the cord. It must be assumed that a process of the tumor extended through the intervertebral foramen and compressed the cord, and that the removal of the main tumor mass allowed the intraspinal portion of the tumor sufficient room to relieve the pressure on the cord. This, however, was conjecture and without operative or autopsy proof.

42. Kredel and Busse, cited by Coenen

CASE 34.<sup>43</sup>—A man, aged 33, previously entirely well, began four weeks before admission to the hospital to have lancinating pains in the lumbar region followed about a week later by difficulty in walking. The paralysis progressed rapidly and on admission to the hospital, there was complete spastic paralysis of both legs, difficulty in the control of the bladder and rectum, increased patellar and Achilles reflexes, marked sensory disturbances over the legs up to Poupart's ligament and to a lesser degree to the umbilicus, and some deformity and pain on pressure in the region of the eleventh thoracic vertebra. The roentgenogram showed a shadow in the thorax to the left of the eleventh intercostal space, which suggested a calcified mass. From the roentgenogram alone a diagnosis of tuberculous spondylitis, with a calcified abscess, was made. There was a decubitus ulcer present which made operation at the moment impossible. In the further course of the condition the spastic paralysis was rather suddenly replaced by a flaccid paralysis of the lower extremities and the development of a cystitis and pyelonephritis, with chills, high fever, etc. Three months after admission, the patient died without having been operated on. The autopsy showed an enchondroma arising from the eleventh and twelfth dorsal vertebrae, which had extended through the intervertebral foramen between these two vertebrae, and had markedly compressed the cord. There was an extensive purulent meningitis.

CASE 35.<sup>44</sup>—The case was one of intraspinal, extradural tumor at the level of the fifth and sixth dorsal segments, which had produced compression of the cord. A roentgenogram taken some time later showed a tumor mass to the left in front of the spine. Operation disclosed a tumor compressing the cord which continued through an intervertebral foramen and enlarged again in the mediastinum. The tumor was called a neurofibroma.

CASE 36.<sup>45</sup>—The detailed history and physical examination are here briefly abstracted. A man, aged 25, was admitted with the complaint of stiffness of the legs and inability to urinate. For three years he had pain in the midregion of his back and to the right of the median line. Two months before admission to the hospital he had a numb feeling in the feet and legs, followed by stiffness in the legs. A month before admission he began to have difficulty in walking, and two weeks before inability to urinate. Examination showed an incomplete spastic paralysis of the legs with exaggeration of the deep reflexes, and a diminution of sensation over the legs and abdomen to the level of the ensiform cartilage. The roentgenogram of the spine showed a rounded shadow in the right side of the chest, extending outward 8 cm. from the midline (fig. 20). There was some erosion of the inner ends of the fifth and sixth ribs. The chest and spine were otherwise normal. A diagnosis was made of lesion of the cord at the level of the fourth thoracic vertebra; intrathoracic (mediastinal) tumor. In the author's opinion, the condition was an intrathoracic tumor with an intraspinal extension.

Dr. Naffziger performed laminectomy at the level of the fourth thoracic vertebra. There appeared an extradural tumor compressing the cord which was perfectly encapsulated. A process of the tumor passed through an intervertebral foramen. The extradural tumor was cut off at the intervertebral foramen and otherwise completely removed. Uncomplicated recovery followed. The pathologic diagnosis was osteochondroma.

One month later, thoracotomy was performed by Dr. Pope, resection of the posterior portions of the fourth, fifth and sixth ribs being done. The capsule of

45. Naffziger, Howard: Personal communication to the author.

the tumor was ruptured in freeing the growth and a thin, gelatinous, bloody fluid escaped. The contents within the tumor capsule were then removed with a curet and sponges. Further dissection of the capsule of the growth showed a pedicle of the tumor disappearing into the intervertebral foramen. This was removed. The empty capsule of the tumor was then packed with gauze soaked in 50 per cent alcohol and a catheter inserted which was led out through the thoracic wall. The wound was closed around the packs and catheter. Recovery followed with improvement in all symptoms.

Fig. 20.—Roentgenogram of the thorax in Naffziger's case showing a tumor of the mediastinum; case 36 in Tumors of Dorsal Region.

CASE 37.<sup>46</sup>—The age and sex of the patient were not given. The symptoms came on spontaneously with pain, and were those of a chronic, incomplete transverse myelitis of the dorsal region. The paralysis was of the spastic type. At operation, a laminectomy in the dorsal region disclosed an extradural fibrosarcoma which was connected through the dura with a second intradural tumor of the same nature and at the same level. The tumor was removed. The cord was somewhat injured in the course of the removal. Convalescence was prolonged, extending over a period of six months. Nevertheless, the patient almost completely recovered from the paralysis.

46. Nonne: *Deutsche Ztschr. f. Nervenhe.* 40-41:161, 1910-1911.

## CASES OF LUMBROSACRAL HOUR-GLASS TUMORS

CASE 1.<sup>40</sup>—A man, aged 43, for two years had lancinating pains in the right hip extending along the outer aspects of the right thigh. Since the beginning of 1917, dull pain and paresthesia developed in the region of the coccyx, and along the outer side of the right leg and foot. Later, he had difficulty in controlling the bladder. Examination showed intense pain in the coccygeal region increased by movements affecting the lower spine and hips. Later, the spine became rigid. There was no spasticity of the legs. The right thigh was atrophic. No sensory disturbances were noted. At operation, the fourth and fifth lumbar laminae were removed. The dura was distended with fluid. An intradural tumor the size of a hazelnut was found covered by the fibers of the cauda equina. A process of the tumor extended through the dura between the fifth lumbar and first sacral nerves. Extradurally, the tumor was intimately connected with the dura so that a piece of this membrane was excised with the tumor. The patient recovered. His symptoms disappeared. At a later date he was found to have disseminated tuberculosis.

CASE 2.<sup>47</sup>—A woman, aged 23, at autopsy showed a reddish, soft mass lying over the posterior and lateral aspects of the cord from the twelfth dorsal to the fourth lumbar vertebrae. The tumor apparently arose from the dura and had grown through it, implicating the pia arachnoid. Laterally, the tumor was continuous with a narrow strip of tumor tissue which extended outward through an intervertebral foramen or behind the lamina of the vertebra and connected with an abdominal tumor which was retroperitoneal in position and attached to the bodies of the tenth dorsal to the second lumbar vertebrae. The mesentery in the vicinity contained many small, whitish nodules. The tumor was called a round cell sarcoma.

CASE 3.<sup>48</sup>—A woman, aged 46, for ten years had pain in the back and the lower lumbar vertebrae. Five years before examination, she began to have weakness of both legs which progressed to a complete paralysis. Examination showed fixation of the lumbar vertebrae and a slight lordosis. There was a depression of the spinous process of the fifth lumbar vertebra and pain on pressure over this region. On rectal examination, there could be felt a tumor the size of a 10 pfennig piece, which was hard, smooth, movable and painful. This mass seemed to come out of the first right sacral foramen. Neurologically, the patient showed paralysis of both legs without marked spasm and anesthesia, with a fairly definite upper level. There were no trophic disturbances. At operation, a tumor the size of a walnut was found lying in the sacral canal and extending from the fifth lumbar to the second sacral arches. The tumor had broken through the dura so that a portion of it was intradural. The extradural portion of the tumor sent a process through the intervertebral foramen which was continuous with the tumor palpable per rectum. The entire tumor was removed. The symptoms of cord compression disappeared. Three weeks after operation, the patient was walking. Sometime later, symptoms returned, and the patient died, nine months after operation, presumably from a recurrence.

CASE 4.<sup>49</sup>—A man, aged 47, had been ill one year and eight months with compression symptoms of the cord. At autopsy, the lower end of the lumbosacral cord was displaced to the left due to a hard, firm tumor, the size of a hazelnut. This tumor presented a smooth surface, was bluish in color, and attached to the

48. Guleke and Rosenfeld, cited by Antoni.

49. Poth: *Inaug. Diss.*, Leipzig, 1911; cited by Antoni.

dura. Several nerve roots were incorporated in it. The tumor was both intradural and extradural, the intradural portion of the tumor being 18 mm long. From the extradural portion of the tumor a process of tumor tissue extended through the intervertebral foramen, between the second and third right lumbar vertebrae. The extradural portion of the tumor was 17 mm long and had attached to it the second lumbar nerve and its ganglions. There is no record of a paravertebral tumor. The pathologic diagnosis was an angiosarcoma. Benda called it a vascular sarcoma of the dura.

CASE 5<sup>50</sup>—A boy, aged 16, presented a tumor of the back which had gradually grown to an enormous size. He suffered with pain in the legs and weakness. A

Fig. 21.—Roentgenogram of spine in a case of hour-glass tumor of the lumbar region showing erosion of the third lumbar vertebrae (personal observation); case 6 under Tumors of the Lumbosacral Region.

large superficial tumor was removed and was considered a lipoma. The patient died following operation. At autopsy, an extradural spinal tumor (angiolipoma) and an intramedullary angioma were found. There was also a fatty tumor containing numerous vessels in the right scapular region, and an angiolipoma of the right kidney capsule. Stookey considered the intradural tumor an extension of the lipoma of the back. There was no definite statement that it traversed the intervertebral foramen.

50. Barenbruch, cited by Stookey: Intradural Spinal Lipoma, *Arch. Neurol & Psychiat.* 18:16 (July) 1927.

CASE 6.<sup>51</sup>—A woman, aged 29, entered the Cincinnati General Hospital on July 21, 1928, complaining of inability to walk and pain in the small of her back. The symptoms dated from the previous August, and began with stiffness of the calf of the left leg, followed by pain in the back which radiated into the left thigh and leg. There followed gradual weakness of the legs leading to an incomplete paraplegia. Examination showed almost total loss of function of the left leg,

Fig. 22.—Lateral roentgenogram of the lumbar spine showing defect in the third lumbar vertebra caused by an hour-glass tumor; case in figure 21 (personal observation).

weakness but not total paralysis of the right leg and considerable atrophy of the left leg. There were disturbances of pain and temperature sense over the left leg, but not of touch. The chest was clear; the abdomen, normal. A roentgenogram of the spine showed a large area of rarefaction, chiefly in the body of the third

---

51. Heuer: Not previously reported.

lumbar vertebra (figs. 21 and 22). A diagnosis of probable extradural tumor at the level of the third lumbar vertebrae was made. Operation was performed by Dr. W. DeW. Andrus on Aug. 9, 1928. An incision from the twelfth dorsal to the fifth lumbar spinous processes was made. In attempting to strip away the erector spinae muscles from the third lumbar spinous process, a tumor consisting of soft, brainlike tissue was found, extending into the muscles of the back. It had apparently extended outward between the laminae and had caused some erosion of the third lumbar spinous process. A bit of tissue was removed from the tumor, immediate section of which suggested a malignant sarcoma. The operation was, therefore, abandoned and the wound closed. The patient was discharged from the hospital unimproved. The pathologic diagnosis (by N. C. Foot) was spongioblastoma multiformae.

CASE 7.<sup>52</sup>—In a child, a ganglioneuroma of the lumbar region was associated with incontinence of the urine and feces, and a trophic ulcer of the perineum. At operation, the tumor was found to send a process through the intervertebral foramen between the last two thoracic vertebrae which apparently compressed the cord. The tumor was removed; the result is not stated. Pathologically, the tumor was a ganglioneuroma.

CASE 8.<sup>53</sup>—A child, aged 4 years, presented a large and malignant nerve tumor (neuroblastoma) which belongs to the group of hour-glass tumors. It lay retro-peritoneally in front of the lower lumbar vertebrae. It was the size of a man's fist and was connected through several intervertebral foramina with an intraspinal tumor the size of a walnut. The treatment, if any, was not stated.

#### CASES OF MULTIPLE OR GENERALIZED TUMORS

CASE 1.<sup>50</sup>—A woman, aged 28, from the age of 13 to 16 years began to have pain in the neck and over the entire body. There appeared numerous subcutaneous tumors which increased in number and size. A definite weakness developed in both arms and legs, most marked in the arms and especially the hands. Examination showed a skin tumor to the right and just above the symphysis. An enormous number of subcutaneous tumors were scattered over the body and especially over the neck in front of, and behind, the sternomastoid from the angle of the jaw to the clavicle. There were also large numbers of tumors over the outer surface of the arms and elsewhere over the body. The patient was intelligent. There was slight paresis of the right side of the face; otherwise, the cranial nerves were normal. There was paresis of all four extremities but no definite paralysis. The cutaneous sensation was diminished. Gait was ataxic. The Babinski sign was positive. In the further course of the patient's illness, the paresis of the extremities increased. The roentgenogram of the spine was negative. At operation, a laminectomy was done and the cervical region explored. At the level of the second to the fourth cervical vertebrae a tumor was found compressing the anterior surface of the cord. One or two nerves were intimately adherent to the posterior surface of the growth. In an attempt to remove the tumor it broke into pieces and was removed in fragments. The patient's condition was poor. The operation was hastily terminated. Death occurred from bronchopneumonia. The tumor removed at operation was considered a neurofibroma. At autopsy, there appeared an extensive peripheral neurofibromatosis. The cords of the brachial plexus were especially involved, but practically all peripheral nerves took part in the pathologic

52. Rapp, cited by Coenen.

53. Anitschkow, cited by Coenen.

condition—the intercostals, the vagi and the sympathetics. In the upper mediastinum were masses of tumors resembling an advanced lymphosarcomatosis, the tumors varying in size from a pinhead to a goose egg. Most remarkable was the picture when the spinal canal was opened. Every spinal ganglion was enlarged to the size of a hazelnut. All the segmental nerves distal to the ganglions were thickened extradurally, except in the sacral region where intradural tumors also were present and of the size of a walnut. In the cervical region the extradural segmentally arranged tumors penetrated the dura and presented in the intradural space as tumors of varying size (fig. 10). These bore a definite relationship to the nerve bundles. The anterior roots were either unchanged or greatly thickened and were not attached to the tumor mass. The posterior roots, however, were closely connected with the tumors. Pathologically, these multiple tumors are called neurofibromas.

# ANATOMIC CHANGES IN THE LABYRINTH SECONDARY TO CEREBELLOPONTILE AND BRAIN STEM TUMORS \*

S. J. CROWE

The Otological Research Laboratory was established four years ago for the purpose of trying to discover something about the underlying causes of the various types of deafness. From a small beginning the laboratory has grown until it now employs eleven salaried assistants, and up to the present time has received from the pathologic department of the Johns Hopkins Hospital and the Bay View Branch of the City Hospitals over 1,100 pairs of temporal bones. Serial sections have been made of each of these specimens. The primary object of the investigation is to examine, with the greatest care and with the most modern instruments, the functional condition of the auditory and vestibular apparatus, and to correlate these observations with the changes seen in the microscopic sections. Many of the patients that enter the hospital in the medical and surgical service with a general systemic disease or a disease of the central nervous system have some disturbance of the function of the auditory apparatus that may be due to purely local causes or may be secondary to the systemic disorder. Thus by examining every patient whose general condition makes it seem likely that he will come to autopsy, my co-workers and I are enabled to study the disturbances in hearing and the microscopic changes in the ear that may be associated with cerebral arteriosclerosis, syphilis, hypertension, hypotension, nephritis, disturbances of the ductless glands, the various diseases of the blood and lesions of the central nervous system.

The material thus collected is also used for teaching, and for the study of the finer anatomy and physiology of the end-organs of the auditory and vestibular system. Under the latter heading Bunch<sup>1</sup> has recently shown by repeated tests on a patient that there is no disturbance in the perception of pure tones or spoken words after a complete excision of the entire right cerebral hemisphere. One of the cases reported (case 1) records an excellent experiment on *tone localization* in the human cochlea, while both the first and the second case indicate that the wallerian law of degeneration does not apply to the ganglion of the cochlear nerve.

## REPORT OF CASES

CASE 1.—*History*.—C. B., a man, aged 48, had a primary carcinoma in the right bronchus with metastases in the ethmoidal, sphenoidal and right temporal bones

---

\* From the Otological Research Laboratory, the Johns Hopkins University.

1. Bunch, C. C.: Auditory Acuity After Removal of the Entire Right Cerebral Hemisphere, J. A. M. A. 90:2102 (June 30) 1928.

Fig. 1.—Audiometer chart showing normal hearing for a subject, between 40 and 50 years of age. This test was not made in a sound proof room. The pitch of the tones tested is indicated at the bottom of the chart; the faintest intensity at which the patient hears the tone is indicated by the figures at the left. The hearing for the right ear at a pitch of 512, for example, is 20 sensation units. This is represented by a small circle on the vertical line marked 512 and on the horizontal line marked 20. The threshold of hearing for the various tones tested on the left is indicated by the crosses. The frequencies that are most used in conversation lie between 256 and 3,000 double vibrations.

Fig. 2 (case 1).—Audiogram of patient with a metastatic carcinoma in the internal auditory meatus on the right that destroyed all of the cochlear nerve except the fibers to the apical coil (figs. 3 and 4). The audiogram for the right ear shows that only two of the whole range of tones tested were heard, namely, 64 and 128. The hearing for high tones in the left ear was impaired; but within the speech range it was approximately normal.

and in the fifth and seventh cervical vertebrae. The chief complaint on admission was cough, hemoptysis and severe pain in the shoulders and neck. The patient said that he had occipital headache and severe "dizzy spells," but that these symptoms gradually disappeared three months previous to admission and had not recurred. He dated his present illness from an attack of pneumonia six months before. During the past five months, he had lost 55 pounds (24.9 Kg) in weight.

*Examination.*—The temperature was 99.8 F.; the pulse rate, 120. The blood pressure was systolic 110 and diastolic 74. The hemoglobin content was 76 per cent.

Examination of the cranial nerves showed the following: Second nerve: vision was good; no choked disk. Third, fourth and sixth nerves: These nerves were normal. Fifth and seventh nerves: These nerves were normal in spite of the fact that a metastatic carcinoma located in the right internal auditory meatus had destroyed a large area of bone and produced a pressure atrophy of most of

Fig. 3 (case 1).—Cross-section of right cochlea showing erosion of the bony wall of the internal auditory meatus due to a metastatic carcinoma; atrophy of the cells of the spiral ganglion, the peripheral nerve fibers and organ of Corti in the basal and middle coils.

the fibers of the cochlear and the central trunk of the vestibular nerve (fig. 3). Eighth nerve: There was approximately normal hearing on the left; marked deafness on the right (fig. 2). Ninth, tenth, eleventh and twelfth nerves: These nerves were normal on both sides. There were no symptoms that suggested a cerebellar lesion. Neither nystagmus nor incoordination of movement was present.

The right ear drum was entirely destroyed due to an infection that had been present since early childhood. There was no complaint of tinnitus. Tuning fork and audiometer tests showed approximately normal hearing on the left, but a complete loss of perception for all tones on the right, with the exception of an octave below and possibly half an octave above 128 double vibrations. The hearing tests, however, were made under difficulties due to severe pain in the chest and

Fig. 4 (case 1).—Normal-looking nerve in the osseous spiral lamina of the apical coil: complete atrophy in the middle coil.

Fig. 5 (case 1).—Apical coil. Compare the osseous spiral lamina, the organ of Corti and the stria vascularis in this coil with the appearance of these structures in the middle coil (fig. 6). An audiometer, tuning fork and voice test made one month before death showed that the patient could hear only a few of the lowest tones in this ear.

the back of the neck. This "island of hearing" in the right ear would have been missed by a routine tuning fork examination. It is not possible to have a total loss of hearing for either high or low tones as a result of an acute or chronic infection that is limited to the mucous membrane of the middle ear or eustachian tube. The drum, together with the malleus and incus, may be destroyed, as sometimes occurs in scarlet fever, with but little impairment of hearing. Ankylosis of the stapes, however, may cause profound deafness, as in otosclerosis, but the high tones are always heard better than the low tones if the lesion is limited to the middle ear.

This patient had a complete loss of perception on the right for all tones above 128 double vibrations owing to the pressure of a metastatic carcinoma on the eighth nerve in the internal auditory meatus. The fact that some of the low tones were heard in this ear was due to the accidental escape of those fibers of the auditory nerve that supply the apical coil of the cochlea. The impairment for 128 double vibrations on the right, as shown in the audiogram (fig. 2), may be due

Fig. 6 (case 1).—Middle coil. Complete atrophy and disappearance of the nerve in the osseous spiral lamina and the organ of Corti. Marked atrophy of the stria vascularis.

in part to the chronic suppuration of the middle ear and destruction of the drum, but the microscopic sections of the inner ear explain clearly why the tone perception in this ear was limited to the low notes (figs. 4, 5, 6 and 7).

Helmholtz and others have inferred from the physical structure of the cochlea—the length of the basilar membrane and thickness of the spiral ligament—that the low toned waves are received and transformed into nerve impulses in the apical coil, the high tones in the basal coil and that midway between these is the area most used in speech perception. This idea has been confirmed by subjecting animals to a constant sound of a known pitch for several days or weeks. Serial sections of the cochlea in such experiments show focal degeneration of the cochlear nerve and organ of Corti, varying in location as the pitch is changed.

Fig. 7 (case 1).—Basal coil. The changes are the same as shown in figure 6, with the exception of the stria vascularis, which is more nearly normal.

Fig. 8 (case 1).—Normal modiolar vessels, atrophic cochlear nerve central to the ganglion, degenerated spiral ganglion and empty canals in the osseous spiral lamina. These canals normally contain the fibers peripheral to the ganglion.

*Comment.*—The accidental escape in this case of a few fibers of the auditory nerve from the pressure of a growing tumor, together with careful hearing tests and satisfactory serial sections of the inner ear all combined to make an interesting experiment on the localization of tone perception in the human ear. This case is of further interest since a lesion of the cochlear and vestibular nerve in the internal auditory meatus results in different types of degeneration. The degeneration of the vestibular nerve extended only to the vestibular ganglion, while that of the cochlear nerve included the cochlear ganglion, the peripheral nerve fibers and the organ of Corti.

The photomicrographs of the labyrinth of this patient are presented because, by chance, they offer an opportunity to make physiologic observations: (1) on the localization of tone perception in the cochlea and (2) on the degeneration of

Fig. 9 (case 1).—Normal looking vestibular nerve and macula of the utricle. In this case, with a lesion of the auditory nerve in the internal auditory meatus, the peripheral nerve fibers and end-organs of the vestibular ganglion are unchanged, while the nerve peripheral to the cochlear ganglion and the organ of Corti has atrophied.

the cells of the spiral ganglion, the peripheral nerve fibers and the end-organ of Corti, secondary to a lesion of the cochlear nerve in the internal auditory meatus.

*CASE 2.—History.*—M. H., aged 9 years, was admitted to the hospital in a semicomatose condition, due to a marked internal hydrocephalus, and died within a few hours after a cerebellar exploration. An inoperable glioma was found at operation. Both the history and the examination were unsatisfactory and incomplete. The case, however, is of anatomic and physiologic interest. The first clinical symptoms were headache, nausea and vomiting, and dated back only four months. The family had noticed no impairment of hearing, and the general condition was such that hearing tests could not be made.

*Autopsy.*—At autopsy the tumor was found to lie within the right cerebellar hemisphere and extended forward into the midbrain. There was no evidence of a growth in the cerebellopontile angle. The microscopic sections of the temporal bones, however, showed a marked difference between the inner ear on the right and that on the left side. On the right, the following changes were observed: 1. There were atrophic changes in the cochlear nerve. 2. The spiral ganglion had almost completely disappeared; a few scattered ganglion cells remained, but they were much shrunken. 3. The peripheral fibers in the osseous spiral lamina were atrophic but had not entirely disappeared as in case 1. 4. The organ of Corti was

Fig. 10 (case 2).—This patient had a glioma in the right cerebellar lobe. There was no tumor in the cerebellopontile angle. Cross-section of the right cochlea shows degeneration of the spiral ganglion. The nerve in the osseous spiral lamina is atrophic but has not entirely disappeared as in case 1. The modiolar vessels are normal. The cochlea on the left is normal in every particular.

represented by a shrunken clump of cells. The microscopic sections of the left temporal bone showed that the cochlear nerve, spiral ganglion, peripheral nerve fibers and end-organs were all normal. The contrast between the two sides was striking. The vestibular nerve, the cells of the vestibular ganglion and the end-organs looked normal on both sides.

It is generally accepted that the cochlear nerve is like a sensory spinal nerve in that a lesion central to the ganglion will be followed by a central degeneration, at least as far as the next ganglion cell; and a lesion peripheral to the ganglion will result in atrophy as far as the end-organ. The cells of a spinal ganglion, however, do not atrophy or disappear after section of either the central or the peripheral nerve trunk. The histologic appearance of the cochlear ganglion in these two cases indicates that this ganglion is an exception to the general law. In the first case, the changes in the inner ear were secondary to a lesion of the cochlear nerve in the internal auditory meatus; in the second case, similar changes were due to a lesion of the auditory pathway within the cerebellum and midbrain.

The experimental work of Wittmaack,<sup>2</sup> in 1911, showed that division of the auditory nerve in the internal auditory meatus, in cats, is followed by atrophy of the cochlear nerve, the cells of the spiral ganglion, the peripheral nerve fibers and the hair cells of the organ of Corti. The degeneration of the vestibular nerve, however, extends only to the vestibular ganglion; the ganglion cells, the peripheral vestibular fibers and the end-organs are normal. In these experiments great care was taken to avoid injury to the internal auditory artery. It is evident from these observations that the cochlear and vestibular nerves differ in their reaction to a lesion of their central fibers. The degeneration of the vestibular nerve follows the wallerian law, while the cochlear nerve is an exception to this law. Knick,<sup>3</sup> in 1912, came to the same conclusion after a long series of experiments on guinea-pigs. The clinical pathologic studies of Lange,<sup>4</sup> Zange<sup>5</sup> and Steurer<sup>6</sup> on tumors that involve the auditory nerve in the cerebellopontile angle tend to confirm the experimental observation that the cochlear ganglion is an exception to the wallerian law of degeneration.

It might be argued that a growing tumor in the cerebellopontile angle in addition to destroying the nerve may also compress the labyrinthine artery, which is generally agreed to be an end-artery, and

6. Steuer, O.: Ueber Beteiligung des inneren Ohres und des Hörnerven bei multipler Neurofibromatosis Recklinghausen, mit besonderer Berücksichtigung der sekundär absteigenden degeneration des Hörnerven, Ztschr. f. Hals-, Nasen- u. Ohrenh. **4**:124, 1923.

that a poor supply of blood together with a marked increase in intracranial pressure could cause the degenerations that have been described in the inner ear.

The two clinical cases reported answer all of these objections and clearly indicate that the changes seen in the cochlear ganglion and peripheral nerve fibers are secondary to the lesion of the cochlear nerve central to the ganglion. By referring to figures 4, 5, 6 and 7, it is seen that the atrophy of the organ of Corti and the nerve in the osseous spiral lamina is limited to the basal and middle coils of the cochlea. In the apical coil the nerve peripheral to the spiral ganglion and the end-organ look approximately normal. Additional evidence that the fibers that supply the apex of the cochlea are intact is furnished by the hearing test made one month before death. This showed that the patient could hear some of the low tones but had absolute deafness for all tones above 128 double vibrations. If these degenerative changes were due primarily to an interference with the blood supply or to increased intracranial or intralabyrinthine pressure, one would expect to find a more uniform distribution of the lesion of the inner ear, and an involvement of the vestibular nucleus and end-organs. In the second case there was a marked increase of intracranial pressure due to an internal hydrocephalus. Whatever effect this has on the labyrinth should be bilateral. In this patient, however, the only changes seen were on the right side and were limited to the cochlear branch of the auditory nerve. It seems clear that the atrophic changes in the spiral ganglion, peripheral nerve fibers and organ of Corti in these two clinical cases were secondary to a lesion of the auditory nerve central to the cochlear ganglion, and that this ganglion is an exception to the wallerian law of degeneration.

# EXPERIMENTAL THROMBOPHLEBITIS AND LYMPHATIC OBSTRUCTION OF THE LOWER LIMB

A PRELIMINARY REPORT \*

JOHN HOMANS  
AND  
ROBERT ZOLLINGER

In the preparation of a paper on thrombophlebitis and its sequelae, read before the American Surgical Association in 1927, one of us attempted to reproduce the disease by injecting a coagulant into an isolated segment of the femoral vein. One attempt out of three was remarkably successful, and the animal developed a typical phlegmasia alba dolens. The swelling appeared two days after the operation, remained at its height for a day or two, and at the end of eight days had disappeared. The whole course of the condition resembled the mildest sort of iliac or femoral phlebitis in the human being. At the postmortem examination it was found that the surrounding soft parts were firmly adherent to the femoral vein in the area between the ligatures which had been placed just above the knee and just proximal to the inguinal ligament, respectively, about 2 inches (5.08 cm.) apart. Only a remnant of a blood clot was found, and even that remnant was not adherent.

An explanation of the lymph stasis which followed the operation seemed to be that the close association of the trunk lymphatics of the limb with the principal veins caused them to be caught in the inflammatory reaction secondary to the thrombophlebitis. The experiment seemed to throw so much light on the nature of phlegmasia alba dolens in human beings that further experiments were planned.

Several years ago, the late Professor Halsted<sup>1</sup> became interested in elephantiasis chirurgica, particularly in the swelling of the arm which followed amputation of the breast. He instigated experimental work on dogs, some of which was carried out with the aid of Mont R. Reid and F. L. Reichert<sup>2</sup> and published by the latter. In this research two observations stand out clearly: 1. Swelling of a limb distal to the point at which all the soft parts except the femoral artery and vein are divided

2. Reichert, F. L.: The Regeneration of Lymphatics, Arch. Surg. **13**:871 (Dec.) 1926.

reunited by suture is due mainly to lymphatic obstruction and is nearly independent of the state of the principal vein; that is, it takes place in spite of the preservation of the vein; when the lymphatics have regenerated across the scar, ligation of the vein does not prevent the swelling from disappearing. 2. The lymphatics which are draining a limb travel in a weaving manner along the principal venous trunks. They draw together about the external iliac vein in the pelvis and pass into the iliac lymph glands proximal to the iliac bifurcation. Such are the relations between the lymphatics and veins in the canine. Bartels<sup>3</sup> described the course of the superficial and deep lymphatics of the human leg and sketches made from his drawings will be found in a previous paper by one of us (J. H.).<sup>4</sup> How the lymphatics of the entire limb can be obstructed by a considerable inflammatory reaction about the common and external iliac veins may be judged from the accompanying sketch

Fig. 1.—Diagrammatic sketch to show the relation between the principal lymphatics and great blood vessels of the hind leg of the dog. This is an idealized combination of Brödel's drawing of Reichert's experiment and a sketch in Pohle's "Das Venensystem des Hundes." The situation of the ligatures used in the experiments is shown. Lymphatic trunks are not drawn accompanying the hypogastric vein, but the proximal ligature is placed central to this vessel on the ground that such lymph channels must exist. For the sake of clearness several small branches of the external iliac and superficial femoral veins are omitted.

made from Brödel's drawing of one of Reichert's cleared preparations. This shows the course of the principal lymphatics and blood vessels of the dog's lower limb.

It may well be implied from Reichert's experiments that the edema which marks a deep phlebitis in man is not due to venous obstruction

3. Bartels, P.: Das Lymphgefässsystem, in Bardeleben: Handbuch des Anatomie des Menschen, Jena 3:195, 1909.

*per se* but to interference with the return of lymph from the leg. Clinical observations bear this out. Following the appearance of pain, usually in the calf of the leg, which marks the onset of a deep thrombophlebitis, the first physical sign of the lesion is not an engorgement of the superficial veins but edema. The leg becomes white, not blue. Indeed it is difficult to cause venous stasis in the leg. If the femoral vein of the human being is tied, the blueness which follows disappears over night. In the dog, ligation of the common iliac and femoral veins simultaneously causes no recognizable change.

All the evidence, then, indicates that the thrombosis of the deep vein plays an indirect rôle in the causation of edema of the leg. It seems probable that this indirect effect is brought about by a periphlebitic reaction, presumably through an inflammatory involvement of the trunk-line lymphatics. Moreover, while a thrombosis of the femoral vein distal to the entrance of the great saphenous conceivably might involve enough lymphatic trunks to cause a noticeable swelling in the calf, it is clear that to bring about edema of the entire leg, the thrombophlebitis must lie in the external or even in the common iliac vein.

With these considerations in mind an attempt was made to induce in the iliac veins a thrombosis of such a nature as to cause edema of the dog's hind leg. To begin with, the early experiment was repeated without success entirely. The injection of thrombosing substances into a segment of the superficial femoral vein itself rarely causes edema, owing to the presence of several veins draining the thigh and buttocks—the deep femoral, and others, evidently accompanied by lymphatics, which join the femoral vein just above the inguinal ligament.

In another set of experiments the external iliac was tied about 1.5 cm. above the inguinal ligament, that is, proximal to the deep femoral branch (the profunda of man) and well down toward the knee. The experiment failed again except when the material injected into the isolated segment was a strongly corrosive substance such as ferric chloride; this caused such a vivid reaction as to produce a typical phlegmasia alba dolens, but it also caused hemorrhage from adjacent vessels, appeared inhumane and accordingly was abandoned. In other animals, an attempt was made to involve the perivenous lymphatics in scar tissue by sprinkling an inert, nonabsorbable powder over the external iliac and femoral veins for a considerable distance. This method, of course, vitiated the purpose of the research, which was to imitate the deep thrombosis of man, but it was felt that it might throw some light on the local reaction. In one case out of two an unmistakable but slight and evanescent edema of the whole leg resulted, but evidently the resulting reaction was not sufficiently violent.

Eventually it was decided to make use of nonsuppurative bacteria, employing the following technic: After the dog was narcotized with

morphine, followed by ether, an incision was made into the abdomen through the lower part of the rectus muscle of one side, and the common iliac and the internal iliac vein<sup>5</sup> were ligated. Then a second incision was made over the femoral vein, and 5 cc. of a broth culture of a non-suppurative streptococcus (viridans) was injected into the vein, every precaution being taken not to soil the surrounding parts. The injection and ligation was made about one third of the way from the knee to the groin, that is, well distal to the deep femoral vein. Just distal to the point of injection, the vein was ligated.

In the four animals thus treated, a phlegmasia alba dolens resulted (fig. 2) which was typical but evanescent. On the second postoperative

Fig. 2—Experimental phlegmasia alba dolens. The swelling affects the paw as well as the upper leg.

day, swelling began in the thigh. On the following day, it was found to have spread to the lower leg and foot. During this time, particularly on the first and second days, the dogs seemed ill, but they recovered their health while the swelling was at its height. This reaction is slightly different from that observed in the animal exhibiting an edematous leg after the injection of muscle juice into the isolated seg-

---

5. As the internal iliac vein has no valves, it seemed probable that the current might be reversed through it after the common iliac had been ligated and that the material placed in the external iliac might thus be drained off. Very likely this is not actually the case.

ment of the femoral vein. In that case, the onset and duration of the swelling were the same, but the dog never seemed ill. The reaction differed even more decidedly from that occasioned by the injection of ferric chloride into the external iliac vein, for in that case the swelling was progressive and permanent.

The postmortem observations on the animals subjected to the injection of nonsuppurative bacteria explain, perhaps, the temporary quality of the lymph stasis. All were killed under ether anesthesia after about twenty hours' introduction of india ink into the paw. In every case there was a distinct local distention with pigmentation of the perivascular lymphatics at the point in the lower part of the thigh at which the distal ligation was performed and the bacteria injected. From this point to the inguinal ligament the soft parts were moderately adherent to the femoral veins (*venae comites*) but no pigment was visible in the tissues. The tissues were more closely adherent to the vein above the inguinal ligament, and as far as the ligature on the common iliac, than below. In two of the animals a clot extended from the upper point of ligation to the upper valve (just above the deep femoral vein) in the external iliac vein, but was adherent to the vessel wall only close to the upper ligature itself. The common iliac lymph nodes were loaded with pigment. The wounds were cleanly healed, so that accidental sepsis did not enter into the experiments.

It may be inferred that the introduction of nonsuppurative bacteria into the isolated segment of the common iliac, external iliac and femoral vein caused a periphlebitic reaction sufficiently extensive to block temporarily the perivascular trunk lymphatics, but that it was so mild that the lymph soon found its way past or through the obstruction. The failure of the clot to adhere elsewhere than at the point of ligation suggests that the wall of the vein was little injured by the bacteria, and perhaps accounts for the fact that the local perivenous reaction was not more severe. Nevertheless it evidently was more severe in the region of the clot above the inguinal ligament than in the femoral vein distal to the ligament where thrombosis did not occur. Possibly thrombosis might have occurred in the femoral vein had the injection of the broth culture been made into both *venae comites* instead of into one.

From these considerations it appears that it is practicable to cause lymph stasis in the hind limb of the dog by an appropriate sort of injury to the principal vein; that a portion of the common iliac vein should be included in this traumatic process; that injury to the vein need not be of great violence to cause a temporary lymph stasis but that it must be of considerable violence to cause a permanent lymph stasis; that chemicals may be used for this purpose but are not easy to control, and that the use of nonsuppurative bacteria offers the promise of successfully causing a chronic lymph stasis of the leg in a dog. This

work will be continued in an effort to discover a simple and humane method of causing in the experimental animal a "milk leg" similar to that so common and disabling in man. The experiments already performed seem to indicate that the cause of phlegmasia alba dolens is a lymphatic obstruction due to the inflammatory reaction around an area of thrombophlebitis, and that the basic lesion is always in the common or external iliac vein, however far it may extend peripherally. By a study of the reaction in the experimental animal a means of ameliorating the disease in human beings may be found.

# THE DIAGNOSIS AND SURGICAL TREATMENT OF CARCINOMA OF THE COLON\*

EMIL GOETSCH  
AND  
ARTHUR GOETSCH

Carcinoma of the colon presents many difficulties in diagnosis and treatment, and as a consequence there is great diversity of opinion as to the surgical procedures which are suitable in the treatment for this condition and which should be generally followed. Clinical facts which aid in the early recognition of this serious malady, therefore, are most welcome, since, with early diagnosis, surgical intervention gives promise not only of immediate relief but of ultimate cure, for reasons to be mentioned later. A number of characteristic signs and symptoms can usually be brought out by a careful history and physical examination. An accurate diagnosis can be made in the great majority of instances before there are severe nutritional and toxic disturbances and before complicating symptoms of obstruction appear.

Since the clinical picture of carcinoma of the colon varies so greatly, the surgical treatment likewise varies. Because of the alarming symptoms and complications which may be present at the first examination, the possible surgical procedures to be adopted must be seriously considered. On account of the variable factors, namely, the clinical condition of the patient and the personal convictions of the surgeon, a definite operative plan suitable in all cases has not been generally adopted.

It is our purpose to report the results of a detailed study of ten cases of carcinoma of the colon and of two cases of pericolic adhesions simulating carcinoma of the colon. The patients were admitted to the Surgical Clinic of the Long Island College Hospital between January, 1920, and February, 1923. On the basis of this study, we believe that a fairly definite and satisfactory operative plan can be adopted in accordance with the status of the patient and the character of the lesion. Confronted by a clinical syndrome resulting from carcinoma of the colon, we believe it is possible to adopt a suitable surgical treatment, whether a one, two or three-stage operation. A comprehensive review of the literature has impressed us with the fact that the information bearing on the diagnosis and treatment of carcinoma of the colon is often limited, fragmentary and indefinite. Surgeons of large experience have often differed as to a satisfactory mode of attack, and therefore have been unwilling to speak in a conclusive manner. In view of the lack of uniformity of treatment recommended in the past, we feel that it might be of value to report our experiences and deductions.

## ETIOLOGY

The etiology of carcinoma of the colon is obscure. Hemorrhoids, fistulas, colitis, trauma and other pathologic conditions have been regarded as predisposing factors. Mechanical relations at the ileocecal valve, the hepatic and splenic flexures, the rectal folds and the anus are believed to predispose to the appearance of carcinoma at these sites. Surgeons have long noted the relatively frequent occurrence of cancer in the acid stomach and colon as compared with the less frequent occurrence of carcinoma in the alkaline small intestine.

## SYMPTOMATOLOGY AND DIAGNOSIS

The symptomatology of carcinoma of the colon is strikingly variable, and at times even vague. Frequently a history of indigestion of an intestinal type can be obtained on diligent inquiry. Among the symptoms and signs especially helpful in diagnosis are lack of appetite, progressive loss of weight, flatulence, colicky pain, pallor, headache, weakness, malaise, anemia and, in the later stages, intestinal toxemia. Later, as the lesion gradually encroaches on the lumen of the bowel, progressive constipation or constipation alternating with diarrhea occurs. However, so long as even a small opening exists, serious constipation may be absent and the fecal current may be advanced without great difficulty or undue peristalsis (cases 3 and 5). In many cases, the earliest symptom is constipation which may be relieved by mild catharsis. Again, there may be periods of obstinate constipation alternating with periods of comfort or followed by diarrhea, with offensive flatus or mucus due to ulceration of the occluding growth and the accompanying enteritis (cases 2 and 8). At times, the attacks of constipation are accompanied by mild distention and gaseous eructations. Annoying pain ranging from dull, aching to cramplike and even knifelike pains may supervene (cases 1, 2 and 4). Pain may be referred to the site of the lesion or to the umbilicus, or may become generalized. As the constipation grows more obstinate, the patient resorts to vigorous and even drastic purgation, which affords less and less relief. Eventually, catharsis may fail entirely and then serves only to cause severe griping and vomiting. As the disease advances, the bowel proximal to the obstruction distends and hypertrophy of the wall with painful peristalsis ensues. Peristaltic waves can often be seen and felt (cases 1, 4 and 11). Distention is usually generalized as distinct from that in the upper part of the abdomen when there is obstruction of the small intestine. Painful peristalsis may be accompanied by characteristic gurgling apparent to both patient and examining physician. These symptoms grow progressively worse. Uncontrollable nausea with foul, fetid breath and vomiting may bring the patient to a stage of almost complete exhaustion.

In some cases, symptoms may not be noticed until a serious acute complication occurs. A patient in good nutritional state and in apparent health may suddenly be seized with complete or almost complete intestinal obstruction (case 5) resulting from the sudden occlusion of the constricted lumen by a mass of undigested food or impacted feces. Inflammatory edema or adhesions at the site of obstruction may add to the difficulties. There may thus be a history of repeated attacks of partial obstruction with subsequent relief. As a result of the progressive narrowing of the lumen, each successive attack becomes more severe. Pain is absent in the early stages, since at this time the lesion is usually confined to the mucosa. In the further course of the disease, fibrosis keeps pace with ulceration, and as a result bleeding may not be serious enough to attract attention, and may be entirely absent.

The pencil stool, so diagnostic of stricture of the rectum, rarely occurs in carcinoma of the colon. The contents of the colon even at the splenic flexure are semisolid, and as a consequence a considerable constriction may take place before the fecal current is appreciably retarded (case 3). The fecal matter is forced through the constriction, the water is absorbed in the lower colon and the rectosigmoid produces a normal stool.

The leukocyte count in cases of obstruction of the colon due to carcinoma is not strikingly abnormal. In our cases, it has ranged from normal to 13,000. A variable anemia, depending on the duration and severity of the symptoms and the accompanying toxemia, is usually present. Again, anemia may be absent entirely. The pulse, respirations and temperature are surprisingly little affected; in fact, they may be practically normal even in the presence of severe obstruction with profound toxemia.

The urine is often normal or may show traces of albumin and acetone with occasional casts. In the severe cases with marked obstruction, the urinary symptoms often indicate marked impairment of kidney function and severe acidosis. The output of urine in the average case is not markedly decreased. In instances of prolonged vomiting followed by depletion of body fluids and acidosis, the urine is highly colored, concentrated and greatly reduced in quantity.

It should be mentioned that occasionally peculiar omental, appendical, colonic and ileac membranes occurring from primary developmental errors may cause clinical syndromes simulating carcinoma of the colon (cases 6 and 7). The resultant partial obstruction leads to stasis and constipation. The patient loses appetite and weight. Absorption of toxins from the large bowel produces anemia. Progressive narrowing of the lumen causes partial or complete obstruction. Roentgen examination reveals a picture not unlike obstruction from carcinoma of the

colon, and the exact diagnosis is made at operation (cases 6 and 7). Certain conditions due to diverticulitis, coloptosis and renal lesions may simulate carcinoma of the colon, but a careful history and physical examination should eliminate any real confusion.

With regard to further diagnostic aids, we feel that a careful roentgen examination should be made in all cases, with the exception of those in which the patient is critically ill from obstruction. Exhaustive diag-

Fig. 1 (case 5).—Anteroposterior view of the colon at the time of the first roentgen examination. The obstruction in the descending colon is not revealed in this picture due to the fact that the upper distended sigmoid loop is superimposed on the growth. A single roentgen examination may thus be misleading.

nostic measures are contraindicated in these instances and emergency colostomy should be performed. The x-ray picture, in addition to revealing the location of the lesion, shows the extent of the dilatation of the proximal bowel and the degree of obstruction. This information is of great help in the subsequent exploration. A single roentgen examination is sometimes misleading. Thus, in a case of carcinoma in the lower descending colon the true lesion was not observed because at the

time of examination the film taken in the anteroposterior direction failed to demonstrate the obstruction due to a large superimposed sigmoid loop (fig. 1). At a subsequent examination the sigmoid loop was shifted to the right, thus uncovering a constricting annular carcinoma of the lower descending colon (fig. 2). The fallibility of a single roentgen examination has been mentioned by Bevan, among others, who stated that "in some cases of carcinoma of the hepatic and splenic flexures, the over-

Fig. 2 (case 5).—Roentgenogram taken in the left anterior oblique position. The sigmoid loop is displaced to the right revealing an annular constriction of the lower descending colon. Compare this picture with that shown in figure 1.

lapping of the shadows of the barium in the bowel made it impossible in the plate to see any filling defect."

#### PATHOLOGY

Carcinoma of the colon occurs usually as adenocarcinoma. Besides the rectum, there seems to be a predilection for the hepatic and splenic flexures and the sigmoid colon. The lesion commences in the mucosa, and in some instances may remain localized indefinitely as an ulcer. Infil-

Fig. 3 (case 2).—Drawing of annular carcinoma of the sigmoid removed at operation Jan. 6, 1922. Note the thick constricting growth and the practically complete obliteration of the lumen of the colon. The great hypertrophy of the wall of the bowel proximal to the growth is illustrated.

tration of the immediately contiguous tissue generally ensues with a tendency to encircle the lumen, thus producing an annular stricture with obstruction (cases 1, 2, 3, 5, 10 and 11). The lesion may form either a solitary, sharply defined, fungoid tumor, or the wall of the bowel may be more extensively involved causing great thickening and sclerosis with conversion of the colon for a variable distance into a thickened, firm, cylindrical tube. It is surprising that the bowel may continue to function without producing great discomfort until complete occlusion with sudden obstruction supervenes (cases 1, 2, 3 and 5). When the growth

Fig. 4.—Photograph of an annular carcinoma of the colon viewed from within the lumen of the bowel. The wall of the bowel itself is everted. The entire circumference of the growth and the protruding granular and papillary margin immediately surrounding the greatly constricted lumen are shown. This is the type of lesion found in several cases in this series

penetrates the wall of the bowel, adhesions to adjacent viscera or perforation with local or general peritonitis may result (cases 5 and 10). The bowel above the tumor is usually involved in a chronic inflammatory process and, depending on the extent of the occlusion, dilates and hypertrophies. The bowel distal to the tumor stands out in marked contrast, being usually normal or actually collapsed (figs. 3 and 4).

Microscopically, the glands in the mucosa are enlarged; the lining cells are hypertrophied and increased in numbers. There may be inva-

Fig. 5 (case 1).—Photomicrographs of a section taken from an adenocarcinoma of the hepatic flexure. The irregularly shaped acini and the abundant fibrosis are shown. Hematoxylin and eosin stain.

sion of the underlying musculature by the carcinoma cells. Irregularly-shaped acini invade the wall of the bowel and are separated by strands of connective tissue in which there are epithelioid, lymphoid and polymorphonuclear cells. The tubules are lined with cells containing large nuclei rich in chromatin and karyokinetic figures. The ulcerated areas contain leukocytes and cellular debris (fig. 5). The regional lymph glands may or may not show metastases. They are often enlarged as

Fig. 6 (case 2).—Roentgenogram of the right tibia showing cortical defect due to metastatic involvement from an adenocarcinoma in the sigmoid. The lesion in this instance appeared unusually favorable for complete removal. A section taken from the tibial metastasis proved on microscopic examination to be adenocarcinoma.

a result of inflammatory reaction rather than from malignant infiltration. Frequently rigid microscopic search fails to reveal any evidence of malignancy (see pathologic report, case 2). This was our experience in four of the ten cases.

It has been generally accepted that there is a relative freedom from early metastases in carcinoma of the colon. Numerous instances are

cited in the literature in which after five years or longer there have been no recurrences following resection of the growth and the regional lymph nodes. The lymphatics of the colon are less abundant than those of the small intestines. This difference in lymphatic supply may possibly explain the relatively late metastases in carcinoma of the colon as compared with malignant growths of the small intestine. It has been stated that in as many as 50 per cent of patients with a malignant condition of the colon, the disease at autopsy is still localized in the bowel. When the tumors produce metastases, nodules appear in the peritoneum, the regional nodes and the liver (cases 8, 9 and 10). Death is usually due to complications, such as intestinal obstruction with perforation, abscess formation and peritonitis.

Madelung expressed the belief that the spread of carcinoma through the lymphatics does not occur as readily when the lesion is at the splenic flexure as it does when the growth is at the cecum or in the ascending colon. In his extensive review of the literature, he found involvement of the liver reported relatively infrequently in the earlier stages of the disease. Distant metastases are also relatively infrequent. However, in one of our cases an interesting metastatic tumor occurred in the right tibia (fig. 6).

#### PRELIMINARY TREATMENT

The care of patients with carcinoma of the colon can be divided into the preparatory and operative treatment. The condition of the patient, when first seen, determines the type of treatment. When the diagnosis is made before the general health of the patient is seriously impaired and before definite symptoms of obstruction have intervened, there need be no hesitancy in undertaking the necessary surgical measures since no special supportive or preparatory measures are indicated (cases 3 and 9).

In case symptoms of obstruction have not been troublesome, there is sufficient time to investigate carefully the general status of the patient. Occasionally, serious anemia may result from a carcinomatous ulcer. Nutritional disturbances may follow extensive metastases. It is, therefore, necessary to take into account the age, the loss of weight, the blood picture, the presence or absence of acidosis, the nature and extent of the growth and the possible signs of obstruction. The patient should be put to bed, a nourishing liquid and soft diet should be given and the bowels regulated by the administration of mineral oil in adequate quantities. Tonics and iron can be given to advantage. In certain cases, transfusions are imperative.

When the body fluids have been depleted by vomiting and when varying degrees of acidosis are present, hypodermoclysis of physiologic solution of sodium chloride, enteroclysis of dextrose and sodium bicar-

bonate solutions and the intravenous administration of 5 per cent dextrose solution are invaluable, and are particularly recommended. These measures, we feel, are often life saving (cases 1 and 2). Sodium bicarbonate by mouth and the administration of liberal amounts of alkaline and sugared drinks as soon as possible after operation help to combat the acidosis and accelerate convalescence.

When patients are seen in the stage of distention and when colostomy does not seem imperative, we are frequently able to relieve distention and even vomiting by means of enemas, stupes, gastric lavage and the introduction of mineral oil through the stomach tube. When the vomiting has been relieved it is well to administer mineral oil in doses of  $\frac{1}{2}$  to 1 ounce at frequent intervals. Nourishing fluids and soft food of high caloric value are then given. We would emphasize the necessity of sustaining the patient, relieving the obstructive symptoms, conserving the body fluids and combating the acidosis. In accordance with the foregoing suggestions, unfavorable cases are frequently converted into relatively favorable ones.

#### OPERATIVE TREATMENT

In planning the technical steps to be followed in any operation for carcinoma of the colon, it is of the utmost importance for the surgeon to realize that unless the extent of operation is kept well within the limits of tolerance, an unfavorable result will almost certainly follow. Exploration to determine the cause and nature of the obstruction may be out of the question owing to the critical condition of the patient resulting from marked obstruction. If it is reasonably certain that the obstruction is in the large bowel, an emergency colostomy under local anesthesia must be the first stage (cases 1 and 2, fig. 7 A). Preliminary colostomy, in addition to rendering the bowel relatively clean for subsequent operative procedures, allows the nutritional state of the patient to be improved and permits the proximal dilated and possibly hypertrophied bowel to regain its tone and contract to normal size. This greatly facilitates subsequent anastomosis and permits firm healing by relieving the line of suture from distention.

When sufficient time has elapsed for the patient to recover his strength, a second-stage operation is undertaken. At this time the site and character of the lesion are determined, and a search is made for metastases in the adjacent retroperitoneal glands and in the liver. In case of extensive metastasis in the regional glands or in the liver, further operative measures are obviously contraindicated.

In carcinoma proximal to the middle third of the transverse colon, without evident metastases, the second stage consists of division of the terminal ileum, ileocolostomy, possible division of the transverse colon just distal to the hepatic flexure and proximal to the ileocolostomy and

Fig. 7.—Diagrammatic drawings illustrating the steps of the three-stage operation when the carcinoma is proximal to the middle third of the transverse colon, and when the critical condition of the patient permits of colostomy only.

*A* illustrates the first stage, namely, colostomy only;

*B*, the second stage, ileocolostomy with or without division of the transverse colon proximal to the anastomosis;

*C*, the third stage, division of the transverse colon (if this has not been accomplished at the second stage), excision of the excluded proximal bowel containing the tumor, and excision of the former colostomy tract.

In case the condition of the patient permits, stage *A* (colostomy) may be omitted, and ileocolostomy is done at once as the first step in a two-stage operation. This procedure was followed in case 3 of our series.

closure of the divided ends of the bowel (fig. 7 B). If the condition of the patient should not permit of this, the division of the transverse colon should be left to the third stage, at which time the excision of the growth and excluded bowel is accomplished (fig. 7 C). The division of the bowel at the second stage has this advantage, that the omentum may be interposed between the divided ends of the transverse colon and placed downward and to the right of the small intestines, so as to separate the latter from the ascending colon. A few interrupted sutures may then be employed to hold the omentum in this position. The marked advantage of carrying out these details is apparent at the third stage when it is possible to mobilize and excise the tumor, ascending colon and hepatic flexure in practically extraperitoneal fashion. The small bowel and the anastomosis scarcely come into view and there is consequently little danger of infecting the general peritoneal cavity. The colostomy tract is also excised (fig. 7 C). There may be some unavoidable soiling which is taken care of by *generous drainage at the site of the old colostomy* (case 2). A patient whose general condition has, as a result of obstruction, necessitated immediate colostomy may not have recovered sufficiently at the time of the second stage to permit ileocolostomy, excision of the growth, adjoining bowel and regional lymph nodes. It is in cases of this kind particularly that we feel it is much safer to operate in three stages. There would be considerable risk in most cases in completing the entire procedure in two stages.

On the other hand, if it has been possible by means of the roentgen examination to determine the site and character of the lesion, and, furthermore, if the condition of the patient is unusually favorable, preliminary exploration is done. Ileocolostomy with or without cecostomy is performed if the growth is proximal to the middle of the transverse colon. In this manner two stages have been combined into one. At the second stage, the operation comprising division of the transverse colon and excision of the proximal excluded portion is completed. This is the type of two-stage operation employed in favorable cases only. In other words, the first two stages of the three-stage operation are combined into one.

In patients with carcinoma of the splenic flexure, we have carried out generous mobilization of the flexure with the adjoining proximal and distal colon in order to facilitate lateral anastomosis after excision of the growth (cases 5, 10 and 11). In instances of obstruction, preliminary cecostomy should be done for reasons already mentioned. The same circumstances govern the types and stages of operation for removal of carcinoma at the descending colon, sigmocolon or in the sigmoid itself. Reference to the diagrams will make the preceding description clearer (fig. 8, A and B).

We have adopted the lateral anastomosis with an outer approximating peritoneal and submucosal suture of fine silk and an inner continuous infolding chromic catgut suture placed in the well known Connell fashion, a previous continuous plain catgut stitch having been used in the muscle layers along the posterior margin of the stoma. The outer approximating silk suture is then continued anteriorly to complete the anastomosis. Fine silk is used to approximate the peritoneum. Occasional mattress submucosal stitches of fine silk are used for reenforcement. We have had no trouble from leakage of the anastomotic line, except in one case in which a cecostomy had not been done (see comment, case 5). A fecal fistula developed and convalescence was consequently prolonged. Cecostomy should have been done in this case.

Fig. 8.—Diagrammatic drawings illustrating the steps in stage operations when the carcinoma is at or near the splenic flexure.

In case the condition of the patient is critical and there is marked obstruction, a preliminary (emergency) colostomy (as in *A*) is established for reasons similar to those governing the conditions in figure 7*A*.

In case the condition of the patient permits, resection of the growth followed by lateral anastomosis (as in *B*) is done, preferably together with a simultaneous colostomy in most cases. It may be necessary to close the colostomy at a third stage.

A generous mobilization of the involved portion of the colon, whether preliminary to anastomosis or excision, cannot be overemphasized. When the growth involves the ascending colon or the hepatic flexure, proper mobilization is important to facilitate excision of the bowel, tumor and regional lymph glands. When the splenic flexure, the descending colon and the sigmoid are involved, sufficient mobilization is necessary to

accomplish lateral anastomosis without tension (case 5, 10 and 11). In removing the ascending colon and hepatic flexure, the parietocolic peritoneum is incised just lateral to the ascending colon. By digital dissection, the colon together with the retroperitoneal fat and lymph glands, is readily elevated. The hepatic flexure and the liberated bowel are then displaced toward the midline. The lymph glands, extending as far upward and medialward as the uncovered duodenum and vertebral column, are removed. The vessels supplying the excluded colon are ligated, the posterior peritoneum is divided, and the mass is removed. Finally, the colostomy is released in case this has been previously established (cases 1, 2, 10 and 11). A few interrupted catgut sutures are used to

Fig. 9.—Diagrammatic drawing illustrating the establishment of a permanent left colostomy in case of inoperable carcinoma of the lower descending colon or sigmoid.

draw the divided peritoneum over the raw surfaces, care being taken not to constrict the duodenum in this procedure as was done in one of our cases.

The omentum can be used to advantage in isolating the small intestines from the operative field preliminary to subsequent operation on any portion of the colon. The safety of anastomosis and excision is thus assured. The omentum can also be used to cover and protect the anastomotic line. A large cigaret drain is placed through the omentum to the anastomosis. Efficient drainage should be instituted whenever there has been soiling with contents of the large bowel because of the

well known infectivity and great toxicity of material derived from the colon (cases 2, 4 and 12). In the event of considerable infection of the drainage tract and of the abdominal wound, early irrigations with physiologic solution of sodium chloride or other mild solutions is of great importance. A patient debilitated by malignant disease and obstruction can ill afford to combat extensive infection.

The Mikulicz operation is used to advantage in the absence of obstruction and when the tumor is localized to a portion of the bowel readily mobilized. When these conditions do not obtain there is danger of mechanical obstruction due to kinking and of peritonitis or abscess formation from pressure perforation. The stage operations are safer

Fig. 10.—Diagrammatic drawing illustrating ileocolostomy without simultaneous cecostomy as a one-stage operation in instances of inoperable carcinoma of the proximal colon. This procedure is indicated when the obstruction is not critical, when liver metastases are present and when the general condition of the patient is still favorable. These conditions obtained in case 9.

in such cases. They secure immediate relief from the obstruction and enable the surgeon to perform a more satisfactory resection at a later date. In the instance of inoperable carcinoma of the lower descending colon and sigmoid, a permanent left colostomy is performed merely for palliation (fig. 9, case 8).

#### SUMMARY AND END-RESULTS

On the basis of a review of the literature and a detailed study of a small series of ten cases of carcinoma of the colon and two cases of obstruction due to pericolic membranes and simulating carcinoma of the

colon, we would emphasize the necessity for early recognition of the disease if favorable results are to be expected. Helpful facts leading to early recognition should therefore be sought.

The symptomatology is largely though not necessarily dependent on the extent of the lesion and varies from a picture of frank intestinal obstruction with marked toxemia to one of little or no disturbance. Hence the physician must evaluate clearly such symptoms as may be present at the first examination. At times there is merely a story of indigestion of intestinal type. One should bear in mind the following symptoms: lack of appetite, progressive loss of weight, mild colicky pain,

Fig. 11 (cases 10, 11 and 12).—Diagrammatic drawings illustrating the steps in the stage operations when the carcinoma is in the lower descending colon or sigmoid.

Excision of the growth, lateral anastomosis and a simultaneous cecostomy are performed in one stage when the condition of the patient is reasonably favorable, and when there is no alarming obstruction, as in *A*; surgical closure of the cecostomy thus becomes the second and final stage as in *B* (case 10).

In the presence of marked obstruction and when the condition of the patient is not favorable, the first stage consists of cecostomy only. Excision of the tumor and lateral anastomosis are reserved for the second stage. Final closure of the colostomy becomes the third stage (case 11).

In case 12 in which a fatal outcome followed excision of the growth, we performed lateral anastomosis and a simultaneous cecostomy (*A*) in one stage. It is our opinion that death would have been prevented had we restricted ourselves to a first stage emergency cecostomy to be followed at a later date by excision of the growth and lateral anastomosis as a second stage. Closure of the cecostomy would then have become the third stage.

pallor, weakness and anemia. Progressive constipation is frequently though not necessarily present even in advanced cases, since this complaint depends to a large extent on the degree of constriction present. Pain and distention suggest obstruction. In the more advanced cases, peristaltic waves, nausea and vomiting make their appearance in the absence of any prodromes. Singularly, acute intestinal obstruction may be the first real annoying symptom. While the presence of blood in the stools is significant in arriving at a diagnosis, its absence by no means precludes the presence of cancer. The leukocyte count, pulse rate, respirations and temperature are usually normal excepting when acute complications arise. Likewise the urine is often normal excepting when marked toxemia, vomiting and depletion of body fluids has occurred, at which times there is acetoneuria and a diminished output.

Roentgen examination is at all times of the greatest help. It reveals proximal distention and stasis long before real obstructive symptoms appear. The great value of the barium enema cannot be overemphasized. In view of the fact that a single roentgen examination may fail to reveal the presence of a lesion, need for repeated roentgen examinations should be appreciated.

Early diagnosis is necessary for successful operative treatment. When this is possible, a cure may be expected in many of the early cases. Proper and effective surgical procedures should be instituted while the disease is still localized. When the condition of the patient precludes an immediate major surgical procedure, preliminary supportive measures are imperative. These consist of hypodermoclysis, enteroclysis and the intravenous administration of dextrose and saline solutions. The status of the patient must be carefully considered before planning the type of surgical measures applicable to his case, for only in this manner can his welfare be reasonably assured. If the tolerance for operation is exceeded, a bad result will most certainly follow. In the critical cases, colostomy may be the only procedure compatible with safety.

When the growth is proximal to the middle third of the transverse colon, the second-stage operation consists of the division of the terminal ileum and ileocolostomy with or without division of the transverse colon proximal to the ileocolostomy. When a third-stage operation is necessary, the growth and the excluded bowel are removed. In the more favorable cases, namely, those in which obstructive symptoms have not been unusually prominent, the first two stages may sometimes be combined into one.

In the case of carcinoma at or near the splenic flexure, the same principles govern. Preliminary colostomy may be necessary as the first stage, in which case, excision of the tumor and lateral anastomosis of the proximal and distal segments are reserved for the second stage. Closure of the colostomy may occasionally necessitate a third stage.

Furthermore, in lesions of the splenic flexure and the descending colon, excision of the tumor and lateral anastomosis is preferable to ileocolostomy or ileosigmoidostomy for the reason that diarrhea and troublesome enteritis are thus prevented.

In all operations on the colon, the omentum can be used to advantage in isolating and protecting the small intestines from the field of operation. Possibility of gross infection is thereby greatly minimized.

In the ten cases of carcinoma reported there were two operative deaths as the result of failure to take full advantage of the principles of the stage operations. The first of these deaths occurred following a Mikulicz operation for carcinoma of the lower colon. Unfavorable conditions previously enumerated existed, and a first-stage cecostomy should have been done and doubtless would have been life saving. The second operative death occurred as a result of failure to apply the principles of the stage operations with true regard for the patient's tolerance. Here again, we believe that a preliminary cecostomy only would have been life saving.

Four patients were living and well, five, seven, eight and eight and one half years following operation, respectively. It is interesting from the point of view of pathology and prognosis that on microscopic examination the regional lymph glands failed to show metastatic involvement. Again the tendency to relatively late metastases in the regional lymph glands in carcinoma of the colon is illustrated.

Four deaths occurred from metastases, one ten weeks, one six months, one ten months and one approximately two and one half years following operation.

It is interesting that in contrast with the negative pathologic observations in the patients living and well, five or more years after operation, the four patients who succumbed to their disease showed metastatic involvement. Two showed extension to the liver in addition to infiltration of the regional glands. In one there were metastatic nodules in the retroperitoneal glands only. No involvement of the regional lymph glands or the liver could be demonstrated in the fourth case. However, in the fourth case a metastatic tumor made its appearance early in the right tibia. Again it is forcibly impressed that an unfavorable prognosis may be expected unless operation is undertaken during the period at which the lesion is still localized to the bowel.

The fact is revealed even in our small series that deferred operation need not necessarily be hopeless since the relatively late regional involvement may permit a favorable outcome in certain instances. Extensive fibrosis in and about the lesion and the absence of abundant lymphatic drainage are doubtless influencing factors in the relatively late regional metastases.

## REPORT OF CASES

CASE 1.—C. W., aged 46, American, colored, single, was admitted to the hospital on Dec. 31, 1919, with the complaint of constipation, vomiting, abdominal pain, headache and weakness. The past history was negative. The present illness began three months before admission with obstinate constipation. It was characterized in the beginning by moderate vomiting which became more frequent and annoying, and later fecal in character. During the past month, abdominal pain and distention with the appearance of intestinal patterns had developed. The patient had generalized colicky pain, extreme meteorism, loss of appetite and loss of weight, 70 pounds (31.8 Kg.), since the onset of the present illness. Drastic catharsis and colonic irrigations were unavailing. Extreme weakness developed.

*Principal Observations.*—On admission, the temperature was 98.6 F.; the pulse rate, 85, and respirations, 23. The patient was markedly emaciated, with low tension pulse and extensive arteriosclerosis. Frequent belching and vomiting of a distinctly fecal odor occurred. The breath had an acetone odor. Great abdominal distention and intestinal patterns, hyperresonance and gurgling were noted. There were 13,400 white blood cells and 75 per cent hemoglobin. The urine showed actone.

The patient was in extremis. Dextrose and sodium bicarbonate solutions were given by rectum. Intravenous administration of dextrose solution and other supportive treatment were given. The clinical diagnosis was probable carcinoma of the colon.

*First-Stage Operation.*—Jan. 7, 1920: The condition of the patient had improved sufficiently to warrant abdominal exploration. A right rectus incision was made. There was distention and hypertrophy of the cecum and ascending colon. A hard, movable, nodular mass, the size of a fist, was found in the hepatic flexure; also a nodule in the neighboring peritoneum. A hasty right colostomy was done. Intravenous administration of saline solution was given during the operation. The condition of the patient was very poor. Relief from distention and improvement of appetite followed drainage through the colostomy. Bronchopneumonia developed five days after operation.

*Second-Stage Operation.*—February 27: The patient had improved greatly. Abdominal exploration was performed through a rectus incision. No visible or palpable metastases were found in the liver. One retroperitoneal nodule was seen adjacent to growth. The terminal ileum was anastomosed to the transverse colon. Excision of the terminal ileum, cecum, ascending colon, tumor mass and part of the transverse colon, together with portions of the mesentery and adjoining lymph glands was performed. The patient was given 500 cc. of 5 per cent dextrose intravenously during the operation and returned to the ward in good condition.

Profuse vomiting and gastric peristalsis developed gradually after operation, as a result of duodenal obstruction. On the fourth day (March 1, 1920), the abdomen was reopened. The duodenum was found stenosed by too close approximation of the peritoneum at the second stage. The duodenal constriction was released. Following operation, the patient began to retain nourishment; the bowels moved freely, and he improved rapidly. He was discharged on May 25, apparently fully recovered from his abdominal complaint.

*Pathologic Report.*—There was a constricting, hard, nodular ring just beyond the hepatic flexure, and distention and hypertrophy of the proximal ascending colon. In its widest portion, the tumor measured 5.5 cm., in its narrowest portion, 3.5 cm. There was central sloughing. One metastatic nodule the size of an olive was in close proximity.

*Microscopic Pathologic Report.*—Sections taken from the metastatic nodule in the retroperitoneal tissues adjacent to the growth, showed a dense fibrotic background in which carcinoma cells are seen in the form of solid masses and alveoli.

*Subsequent Report.*—Feb. 4, 1923: The patient has been entirely well since his operation and has gained in weight. At this date he weighed 175 pounds (79.4 Kg.). Abdominal examination revealed no areas of tenderness or palpable masses. The edge of the liver could not be felt. The patient was free from any complaints that might be referable to his former condition.

*Comment.*—This case represents an extreme example of obstruction of the large bowel. Any surgical procedure of greater extent than colostomy would have been incompatible with life. The necessity for supportive and prophylactic treatment (enteroclysis, hypodermoclysis and intravenous injections) is illustrated. The preliminary colostomy enabled the patient to improve sufficiently to endure a major secondary procedure. Had he been in any less favorable physical condition at the second stage, it would have been wise to have stopped with a short-circuiting ileocolostomy to be followed at a later date (third stage) by excision of the tumor and excluded bowel (see comment in case 2).

CASE 2.—J. L., aged 57, white, married, was admitted to the medical service on Oct. 6, 1920, complaining of abdominal pain, weakness, loss of weight and vomiting. The family and past histories were negative, except for cancer of the breast in one sister. The present illness began a year and a half before examination, when the patient noticed slight, recurring, transient pains in the region of the umbilicus. These pains increased in frequency and severity. Recently, they had become colicky and even stabbing. Vomiting, nausea, griping and anorexia had developed in the past four weeks before admission to the hospital. There were alternating attacks of constipation and diarrhea, but no mucus or blood in the stools. The patient lost 16 pounds (7.3 Kg.) in weight in a year and a half. Profound weakness developed.

*Principal Observations.*—On admission, the temperature was 100 F.; the pulse rate, 90, and respirations, 25. Marked dyspnea, great emaciation and fetid breath were noted. The abdomen was scaphoid. Visible peristalsis was not present. No masses were felt. The urine showed acetone. There were 9,640 white blood cells and 71 per cent hemoglobin. The stomach contents showed an absence of free hydrochloric acid. Roentgen examination on Oct. 7, 1920, by Dr. Bell, showed a filling defect in the proximal portion of the transverse colon.

On the day after admission, the patient had an attack of continuous vomiting with severe abdominal pain, and showed great prostration. On October 15, he asked to go home "to die." He was readmitted to the medical service on October 19, where he was given liberal supportive treatment (enteroclysis, venoclysis) for the next few days.

*First-Stage Operation.*—Oct. 22, 1920: The patient's condition, though slightly improved, contraindicated extensive operation. A hasty cecostomy was done as an emergency measure through a McBurney incision. Twenty-four hours later, the cecostomy was completed by actual cautery. There was an immediate escape of gas and foul-smelling semisolid fecal matter. Marked progressive improvement in appetite and general nutrition, with complete remission of pain and nausea, ensued.

*Second-Stage Operation.*—November 10: Ileocolostomy was performed. The patient was decidedly improved. Abdominal exploration was made through a liberal right rectus incision. A mass as large as a fist, hard and fibrotic, was found just below the hepatic flexure. A few enlarged glands were noted in the omentum. Resection was not warranted at this time. The ileum was divided 6 inches (15 cm.) from the iliocecal valve and implanted into the transverse colon slightly to the left of the midportion. A large cigaret drain was placed to the line of sutures. The condition of the patient was fair at the end of the operation. He improved rapidly.

*Third-Stage Operation.*—December 15: The colostomy was carefully obscured from the operative field. The abdomen was entered through a long right rectus incision. The parietocolic peritoneum was incised, and the cecum, ascending colon and transverse colon, including the tumor mass, were freely mobilized by digital dissection. The bowel near the cecostomy was then freed from the abdominal wall, and finally the part of the terminal ileum that was left behind at the former operation, together with the appendix, cecum and ascending colon (as far as the ileocolostomy), were removed en masse. One large cigaret drain was inserted through the former colostomy to the right kidney fossa. The patient endured the operation very well. Saline solution was administered subpectorally.

Following the operation, there was gradual progressive improvement. A rather badly infected drainage tract delayed the convalescence somewhat. On Jan. 12, 1921, the patient was allowed to leave the hospital. He seemed quite well.

*Gross Pathology.*—At the hepatic flexure there was a large, rounded, firm mass almost completely occluding the lumen of the bowel and converting it into a small tunnel about 1 cm. in diameter and 4 cm. in length. The bowel proximal to the tumor was generally hypertrophic and distended in contrast to the distal portion which is collapsed and more nearly normal.

*Microscopic Pathology.*—Section from the wall and edge of the ulcerated growth showed great numbers of irregularly-shaped acini extending downward to a very considerable depth and separated by strands of connective tissue in which there were epithelioid, lymphoid and polymorphonuclear cells. Irregular chromatin figures occurred here and there in the irregularly arranged columnar cells. The normal structures of the bowel wall had been destroyed at the deeper levels. The lymph glands adjoining the growth and at some distance from it failed to show any evidence of metastases on microscopic examination.

*Subsequent Report.*—Feb. 4, 1923: The patient reported that he was eating a full diet and the movement of his bowels was regular. He weighed 132½ pounds (60.15 Kg.).

Jan. 4, 1929: The patient looked well and stated that he had maintained his weight without difficulty. Although he was 65 years of age, he looked much younger. At this time the abdominal examination was entirely negative for a demonstrable pathologic process. There were no hernias. Liver dulness was within normal limits. He seemed entirely well.

*Comment.*—As in the previous instances, this case also shows the advisability of conservative surgical treatment of a patient seriously ill with carcinoma of the colon, who could obviously not tolerate a major surgical operation. In our opinion, a cecostomy in this case was the only surgical procedure that was compatible with survival. The colos-

tomy relieved the obstruction and permitted improvement of the nutrition to such an extent that the necessary further steps could be undertaken safely in stages. At the time of the second-stage operation, the patient, though greatly improved, could hardly have survived an extensive resection. Hence, we stopped with ileocolostomy with exclusion of the obstructing mass and proximal bowel.

*CASE 3.*—J. M., a man, aged 62, boilermaker, white, married, was admitted to the hospital on Oct. 27, 1920, complaining of soreness over the abdomen with occasional attacks of acute pain in the right upper quadrant, and loss of weight. The present illness began two years previously with occasional pains in the abdomen. The pains became more severe and were occasionally associated with nausea and vomiting. Thirteen months previously, cholecystostomy and appendectomy were performed. One month after operation, pain in the right upper quadrant returned. Anorexia had been present for many months. In the last three years he lost from 30 to 40 pounds (13.6 to 18.1 Kg.) in weight. Dyspnea was noted on exertion. There was no history of blood in the stools, griping or visible peristalsis.

*Principal Observations.*—On admission, the temperature was 98.6 F.; the pulse rate, 85; respirations, 22. The patient appeared well preserved but slightly anemic. The abdomen contained no palpable masses or tender areas. There were 7,200 white blood cells and 65 per cent hemoglobin. Roentgen examination revealed a slight pyloric obstruction with six hour retention (thought to be due to possible adhesions from the previous operation).

*First-Stage Operation.*—Oct. 29, 1920: Exploratory laparotomy was done through a right rectus incision. There were numerous adhesions. Regional exploration revealed a large hard, firm and fibrotic mass the size of a fist at the hepatic flexure. On releasing the adhesions, free mobilization of the colon was possible. The six hour retention evidently had been due to the encroachment of this growth on the duodenum. The terminal ileum was divided at about 7 inches (17.7 cm.) from the ileocecal valve and the proximal end was implanted into the transverse colon by lateral anastomosis. It was felt that excision of the excluded bowel could not be attempted in safety at this time. One cigaret drain was placed to the line of suture and the wound was closed.

Continuous improvement took place, and after the lapse of one month the patient was in condition for the second stage.

*Second-Stage Operation.*—November 29: The abdomen was entered through a large right rectus incision. The transverse colon was divided distal to the tumor and proximal to the anastomosis. The terminal ileum, cecum, ascending colon, tumor and part of the transverse colon were removed en masse. One large cigaret drain was placed in the kidney fossa. Only a few enlarged glands were encountered in the omentum. There was no evidence of metastasis to the liver. The tumor was firm and scirrhous in character, without extensive ulceration. Saline solution was administered by hypodermoclysis. The patient's condition seemed excellent.

The postoperative recovery in this case was uneventful, and on December 11, twelve days after the last operation, the patient was discharged.

*Pathologic Report.*—The excised tumor was a typical adenocarcinoma and in general was like the lesions described in cases 1 and 2. The regional glands contained no demonstrable carcinoma cells. The detailed report, therefore, is omitted.

*Subsequent Report.*—Feb. 4, 1923: The patient stated that he had been feeling exceedingly well and had been working at his former occupation during the past year and a half. He weighed 162 pounds (73.5 Kg.), which is 10 pounds (4.5 Kg.) above his best weight previous to his present illness. He had on the average three bowel movements a day. Palpation revealed no tenderness or masses in the abdomen.

*Comment.*—The history of a previous operation on the gallbladder, together with the roentgen diagnosis of pyloric stenosis with retention, led us to make a provisional diagnosis of pyloric and duodenal adhesions. We feel that a complete roentgen examination including a colon enema of barium sulphate would have established the diagnosis before operation. The case also illustrates that in certain instances the lumen of the bowel may shrink to surprisingly small proportions without producing serious signs of intestinal obstruction.

*CASE 4.*—Mrs. H. L., a housewife, aged 42, was admitted to the hospital on Feb. 3, 1921, complaining of colicky abdominal pain, nausea, vomiting and obstinate constipation. The present illness began two years previously with constipation and frequent belching. One and a half years ago, she had an attack of colicky pain lasting twelve hours. She also had indefinite attacks of abdominal discomfort. About five weeks before admission, she had an attack of colicky pain with frequent gaseous eructations, but unassociated with nausea or vomiting. Pain and constipation continued to be unrelieved by catharsis or enemas. On the fifth day of her attack, enemas were returned practically clear. On the sixth day, she continued to have severe "rumbling" pains. The following morning, there were severe nausea and vomiting of greenish-brown material.

*Principal Observations.*—On admission, the temperature was 99.6 F.; the pulse rate, 75, and respirations, 25. Great emaciation and pallor were noted. The respiration was of the thoracic type. The abdomen was distended from the umbilicus downward, and intestinal patterns were readily seen. There was severe tympanites. The abdomen was not especially tender to palpation, nor were there any palpable masses. There were 8,400 white blood cells and 80 per cent hemoglobin. The urine showed a trace of albumin and was positive for acetone. The roentgen examination, made by Dr. Bell, indicated obstruction in the lower descending colon.

By means of mineral oil by mouth, turpentine stupes and enemas, the abdominal distention was relieved, and the patient was able to take fluids.

*First-Stage Operation.*—Exploratory laparotomy; Mikulicz colostomy, Feb. 7, 1921: A left rectus incision was made. Coils of intestines under tension were found, and exploration was, therefore, difficult. An obstruction due to a scirrhus, annular growth, was found in the lower descending colon at the junction with the sigmoid. No definite metastases were apparent in the mesocolon, but several normal-looking glands were noticed. The tumor was mobilized, and a Mikulicz operation was performed through a left inguinal incision.

February 8: The proximal and distal loops of the colostomy were becoming gangrenous. Distal and proximal portions of the excluded gut together with the mass were excised by electrocautery. Immediately gas and a steady stream of soft, foul, semisolid fecal matter escaped and afforded great relief to the patient. Later, extreme tenderness developed lateral to the colostomy. Vomiting supervened. Partial retraction of the bowel followed.

February 9.: The patient continued to vomit. The general condition became decidedly critical. The temperature was 99.6 F.; the pulse rate, 96, and respirations, 24. There was a definite reddening of the entire left flank and lumbar region with an escape of foul-smelling pus from the wound. There was evidence of infection of the abdominal wall with abscess formation.

February 17: Ten days after operation, the patient died from intestinal obstruction, infection and local peritonitis.

*Comment.*—We are of the opinion that this patient could have been saved by a more rigid application of the principles which governed the previous cases. Though seriously ill, she was by no means in such a precarious condition as obtained in cases 1 and 2. In another similar case, we would do a preliminary emergency cecostomy to relieve the intestinal obstruction and allow the nutritional status of the patient to improve so that a well planned secondary procedure could be undertaken with safety at a later date. The secondary procedure would then probably consist of excision of the tumor with lateral anastomosis in much more radical fashion than is permissible by the Mikulicz operation. The cecostomy could be closed by a relatively minor operation as a third stage if necessary, in case of failure to close spontaneously.

CASE 5.—W. J. M., a man, aged 45, an engineer, white, married, was admitted to the hospital on May 7, 1921, complaining of colicky abdominal pain, vomiting and constipation. The family and past histories were unimportant, except for constipation during many years. He had to use cathartics every two or three weeks. The present illness began two days previous to admission, when he had slight colicky abdominal pain, but he ate three meals as usual. He had taken a cathartic the previous night, and had a bowel movement the following morning. The morning before admission his pains increased, but in spite of this he ate his breakfast. In the evening, the abdomen became distended. Various kinds of cathartics and food were vomited soon after ingestion. The passing of gas by mouth and rectum relieved his distention somewhat.

*Principal Observations.*—On admission, the temperature was 99.4 F.; the pulse rate, 80, and respirations, 20. The patient was well developed and well nourished, and seemingly not very ill. The abdomen was moderately distended but was not tender to palpation. There was some muscle resistance. No masses were felt. The white blood count was 8,600. The Wassermann reaction was negative.

By means of mineral oil by mouth and repeated enemas, the distention was greatly reduced, and the patient was able to take fluids well. The stools were very dark and strongly positive for occult blood.

May 10, 1921; The results of the general examination were extremely satisfactory.

May 12: Roentgen examination showed a constriction in the upper descending colon with passage of barium sulphate through a narrow tunnel about the size of the little finger. The first series of roentgenograms had been negative, owing to the fact that the omega loop of the sigmoid appeared in the anteroposterior plane of the abdomen, thereby obscuring the real picture. By tilting the patient to the right side at a subsequent examination, the omega loop was made to fall into the horizontal left-to-right plane of the abdomen, and thus a stricture in the upper sigmocolon was demonstrated.

*Operation.*—May 18: A one-stage operation was performed with the patient under gas-oxygen ether anesthesia, a left rectus incision being made. Exploration revealed a hard, irregular mass in the lower portion of the descending colon. There were no apparent metastatic nodules. The splenic flexure and descending colon were easily mobilized. The growth was removed, together with liberal zones of proximal and distal normal-looking bowel. A lateral anastomosis of transverse colon and sigmoid was then made. The large omentum was placed over the small bowel, thus practically walling off the descending colon from the peritoneal cavity. Appropriate drains were placed to the line of suture.

May 26: The patient continued to improve and took nourishment well. The wound had been draining rather freely, and on this date there was a discharge of fecal matter through the drainage tract.

June 7: The fecal fistula had closed.

July 20: The wound healed, and the patient was discharged in excellent condition.

*Gross Pathologic Report.*—There was no great difference in the character of the wall of the bowel proximal and distal to the growth. There was a hard, irregular mass, to which was attached an area of fat, which when elevated exposed a perforation in the wall of the bowel. This perforation was in the center of the growth. When the bowel was opened, an irregular, oval, ulcerated growth with central ulceration measuring 5 by 6 cm. appeared. The growth did not extend around the entire circumference of the bowel. There were no evidences of gross glandular metastases.

*Microscopic Pathologic Report.*—Sections from the border of the ulcer showed irregular, branched, tortuous tubules lined by two, three, four or more layers of cells extending downward into the depth and invading the musculature of the bowel. The nuclei were of all shapes and sizes, with rich chromatin and numerous karyokinetic figures. The tumor gave the appearance of a highly malignant adenocarcinoma.

*Subsequent Report.*—June 22, 1928: The patient reported back from Scotland, approximately seven years after operation for carcinoma of descending colon. He weighed 200 pounds (90.7 Kg.). There was a wide operative scar, no herniation, and no constipation. He had a good appetite and considered himself entirely well.

*Comment.*—This case is interesting in that intestinal obstruction came on suddenly as the very first real symptom in a man in apparently excellent health and in good physical condition. The need for painstaking and careful thought and exhaustive diagnostics is evident from the fact that the man, within three days following the onset of his illness, was made free from all his complaints by ordinary eliminative measures, and hence would appear not to have been very seriously ill. The case, furthermore, demonstrates that a single series of roentgenograms may be entirely misleading (cf. foregoing).

While the end-result in this case was very satisfactory, we are of the opinion that a cecostomy, either as a preliminary measure (first stage) or as a "safety valve" in conjunction with the anastomosis, would have been a wiser procedure. A cecostomy would have relieved the strain on the suture line, and a subsequent fistula would thus have been prevented.

*CASE 6.—Partial obstruction of the colon of benign origin.*

Mrs. L. A. S., aged 60, a housewife, white, was admitted to the hospital on Dec. 7, 1920, complaining of weakness, anemia, loss of weight and constipation. The present illness commenced eight weeks before admission with vertigo when she was getting up in the morning. Progressive weakness followed. She had lost 24 pounds (10.9 Kg.) of weight since the onset of the present illness. In the eight weeks before admission, there had been a marked tendency to constipation with increasing demand for cathartics. Anorexia developed recently. She suffered from some nausea but no vomiting. There was no blood in the stools. She had some gastric discomfort with belching.

*Principal Observations.*—On admission, the temperature was 98.6 F.; the pulse rate, 110, and respirations, 25. The patient was well developed and obese. She felt no discomfort. The abdomen was large, rounded and flabby, but there was no definite tenderness or muscle spasm. There were no palpable masses. There were 9,000 white blood cells and 80 percent hemoglobin. The urine was normal.

Roentgen examination indicated intestinal obstruction due to a lesion, probably malignant, in the first portion of the ascending colon. The cecum and lower colon were greatly distended and communicated with the upper ascending colon by a narrow constricted "tunnel."

*Operation.*—Dec. 22, 1920: With the patient under gas-oxygen-ether anesthesia, abdominal exploration was made through a right rectus incision. The cecum was found covered with adhesions, and at a level of about 5 inches (12.7 cm.) above the ileocecal valve, there was a marked narrowing of the lumen of the bowel due to constricted vascularized adhesions running from within outward to the parietocolic peritoneum and deriving a definite blood supply from the mesenteric circulation. On release of these adhesions, the bowel distended to its normal size. No further abnormalities were found. The etiology of these peculiar pathologic formations was not apparent. Certainly, they were not due to appendicitis.

The patient made an uneventful recovery with freedom from her preoperative complaints. She was discharged, well, on Jan. 10, 1921.

*CASE 7.—Partial obstruction of the colon of benign origin.*

Mrs. B. B., aged 42, housewife, was admitted to the medical service on Sept. 26, 1921, complaining of epigastric distress, dizziness, constipation, loss of weight, loss of appetite and nervousness. The family and past histories were negative. The onset of the present illness was slow and indefinite, approximately two and a half years before admission. At this time, the patient had attacks of epigastric distress and a feeling of dizziness and faintness during the attacks. During the past year she had obstinate and progressive constipation. There was one attack of diarrhea nine months previous to admission. She noticed mucus but no blood in her stools. She had lost 52 pounds (23.6 Kg.) in weight during the past eleven months.

*Principal Observations.*—On admission, the temperature was 98.6 F.; the pulse rate, 64, and respirations, 20. The skin was loose and indicated considerable loss of weight. The mucous membranes were pale. The abdomen was devoid of any tender areas or masses. The results of pelvic examination were negative. The blood counts at various times showed anemia. There were 7,800 white blood cells and 55 per cent hemoglobin. The urinalysis and Wassermann reactions were negative.

Oct. 11, 1921: Roentgen examination, by Dr. Bell, indicated chronic obstruction of the upper ascending colon.

October 17: The patient was transferred for operation from the medical service to the surgical service. The loss of weight and the roentgen observations indicated a probable malignant condition.

*Operation.*—October 19: With the patient under gas-oxygen ether anesthesia, the abdomen was entered through a right rectus incision. The cecum and ascending colon were found extensively dilated, as indicated in the roentgen observations. Near the hepatic flexure, there was a definite band of adhesions commencing laterally, circumventing the bowel and causing a constriction by traction and narrowing of the lumen. Numerous vascularized adhesions running from the lateral parietes over the colon were noted. On loosening these formations, the normal lumen of the bowel was reestablished. There being no further abnormal observations, the abdomen was closed without drainage. The etiology of the peculiar pathologic formations as in case 6, was not clear. The convalescence was uneventful, and the patient was discharged on November 4, free from all preoperative complaints.

*Comment.*—Cases 6 and 7 do not properly belong in this series, but illustrate the necessity of a careful differential diagnosis. The history of loss of weight, constipation and anemia, together with the roentgen observations, made us lean to the diagnosis of obstruction from a malignant growth, in both cases. The narrowed lumen undoubtedly led to constipation and stasis. The resultant intestinal intoxication with absorption may have accounted for the loss of weight, anemia and general cachetic state.

As a possible cause for the unusual vascular formations noted in cases 6 and 7, we may say that in general, the etiology of adhesions is quite apparent in the majority of instances, particularly at operation. Ordinarily, it is customary to consider peritoneal adhesions as the result of peritoneal inflammation in response to injury. The cause may be mechanical or in response to inflammatory disturbances in the adjacent viscera.

Riedel (reported by Harvey) in 1894, first called attention to the fact that omental, appendical, colonic and ileac membranes occurring from primary developmental errors, might cause colicky pain and other symptoms of partial obstruction. He suggested that such membranes might be due to dragging of the colon on the mesentery with rupture of the supporting fibers and their accentuation by subsequent repair. Lane conceived the idea that these structures are merely an evolutionary response to the erect posture. Toldt and others, according to Harvey, have shown that the omentum at about the sixth month of fetal life may extend as far down as the cecum. Ordinarily, the omentum extends on the right approximately to the hepatic flexure provided the omentum has involuted properly. In rare instances, an omental process may extend well over and down the ascending colon and even fuse with the right parietocolic peritoneum, and it is thought by some that the persistence of the omental process and its fusion with the parietal

peritoneum accounts for various abnormal membranes. By a failure on the part of the omental process to keep pace with the descent and growth of the colon, angulation and kinking may occur which results in a formation of vascular bands and adhesions.

By exclusion, we would assume that the unusual vascular bands described in cases 6 and 7 were due to developmental defects and that they were capable of producing a clinical picture simulating carcinoma of the colon with partial obstruction.

These two cases (6 and 7) are included in this analysis because of the many points of similarity between them and the cases of obstruction produced by carcinoma and because of necessity of differential diagnosis.

CASE 8.—W. D., a man, aged 64, a typesetter, was admitted to the medical service on Jan. 13, 1922, complaining of frequent bowel movements with blood and mucus. His illness began about four years before admission when he had diarrhea lasting ten days, with passing of blood and mucus. Three months before, he had periods of alternating constipation and diarrhea with passing of blood clots and mucus. He lost 23 pounds (10.4 Kg.) of weight. Three weeks before, cramps developed in the lower half of the abdomen, mostly on the right side and associated with increasing diarrhea. No marked distention occurred. At the time of admission, he was totally incapacitated.

*Principal Observations.*—On admission, the temperature was 99.2 F.; the pulse rate, 110, and respirations, 20. The patient was markedly undernourished, anemic looking, and showed a marked loss of weight. Moderate distention of the abdomen was noted. There was muscle spasm but no real rigidity. An indefinite, hard mass was palpable in the lower left quadrant. There were 7,200 white blood cells and 62 per cent hemoglobin. Urinalysis and the Wassermann reaction were negative. The stomach contents showed hypochlorhydria. The stools contained occult blood. The roentgen examination, by Dr. Bell, showed an obstruction of the lower colon.

The patient was given the usual preparatory treatment.

*Operation.*—Jan. 20, 1922: The abdomen was explored through a left rectus incision. An irregular and immovable mass the size of a fist was found in the sigmoid. There were numerous metastatic nodules in the liver. A palliative left inguinal colostomy was made through the exploratory incision. Abdominal distention supervened. The everted loop of gut was therefore opened by electrocautery. An escape of gas and some fecal matter followed and the discomfort and distention were almost immediately relieved. The patient began to take food in increasing quantities.

Owing to his greatly weakened and cachetic condition, convalescence was necessarily very slow and troublesome. On Feb. 19, 1922, he was in a decidedly better nutritional state and he was sent to a convalescent home for further care.

*Subsequent Report.*—The patient died from general cachexia and myocardial insufficiency two weeks after his discharge from the hospital.

*Comment.*—This case is interesting in that it is the first instance in our series in which the tumor was palpated through the abdominal wall. A striking feature was the fact that four years previous to entrance to the hospital the patient had severe diarrhea which was followed by a

long interval of comfort. This fact emphasizes the necessity of an early careful diagnostic routine, for it is highly probable that had this patient been given the benefit of thorough clinical and roentgen examinations four years before, a favorable outlook would have been possible. This case illustrates further the utter hopelessness of carcinoma of the colon with metastases, when the only measure of relief that can be given is a colostomy to prevent death from intestinal obstruction.

CASE 9.—Mrs. A. B., aged 64, was admitted to the hospital on Feb. 5, 1922, complaining of weakness, pain in the right side and vomiting. The past history was negative. The present illness began a year before admission with occasional cramplike pains in the lower part of the abdomen. The cramps occurred three or four times a week followed occasionally by diarrhea. Constipation occurred, especially during the past three months. Five weeks before, she had severe pain in the right side of the abdomen followed by vomiting which continued three days. Enemas failed to produce any bowel movements. She lost some weight. She had never vomited blood or passed blood by rectum. Occasionally, the stools were rather dark. She suffered greatly from headaches and weakness.

*Principal Observations.*—On admission, the temperature was 98.6 F.; the pulse rate, 80, the respirations, 20; she weighed 206 pounds (93.4 Kg.). The patient was very obese and senile in appearance. The abdomen was soft, flabby and redundant. To the right of and slightly above the umbilicus, there was a hard, readily palpable, smooth, tender mass about the size of an ordinary grapefruit. Urinalysis and the Wassermann reaction were negative. The stool was positive for occult blood (three occasions). The were 9,600 white blood cells and 75 per cent hemoglobin.

Feb. 11, 1922: Roentgen examination showed an obstruction due to a definite narrowing in the first portion of the transverse colon with dilatation of the proximal portion of the large bowel, particularly the cecum.

*Operation.*—February 11: Exploratory laparotomy and ileocolostomy were performed. The abdomen was entered through a right rectus incision. A hard, firm and scarred mass as large as a double fist, was found in the first portion of the transverse colon. The liver contained a number of small, hard metastatic nodules and a single one as large as an egg. The terminal ileum was divided about 2 inches (5 cm) from the cecum. Lateral anastomosis of the terminal ileum and transverse colon was performed well beyond the mass (fig. 10). Further stage operations could not be planned in the presence of involvement of the liver. One large cigaret drain was placed to the line of suture.

The patient reacted fairly well, but on the second day vomiting was rather troublesome and lavage, hypodermoclysis and other supportive measures had to be used. The following day, she showed signs of basal pneumonia. Convalescence was thus greatly retarded, and healing was sluggish owing to the adiposity.

March 12: The patient had fully recovered from her respiratory complication, showing only slight weakness. She had frequent loose bowel movements, which showed a tendency to become fewer and more concentrated. The wound was healing, and the patient was discharged on this date.

*Pathologic Report.*—The pathologic report showed adenocarcinoma similar to those previously described in pathologic reports (cases 1 and 11). Regional metastasis showed carcinoma cells in great abundance. The detailed report is omitted.

*Subsequent Report.*—Aug. 15, 1922: The patient died six months after the operation. Death was due to extensive hepatic involvement and myocardial insufficiency. Intestinal obstruction did not occur.

*Comment.*—This case further illustrates the extreme variability of carcinoma of the colon. It shows a very obese patient suffering from rather advanced carcinoma of the colon with metastases to the liver, in spite of a history of relatively short duration. The loss of weight had been little, if any. It was the second case in which the mass was palpated before operation. From the point of view of operation, the patient was apparently an unfavorable risk, not because of her carcinoma, but rather for the reason that any obese person bears abdominal exploration rather poorly. The surprising fact at operation was the discovery that in spite of the favorable general condition, it was the second case in which the hope of a radical cure was absolutely out of the question. The operation was thus designed merely to relieve obstruction, to add to the patient's comfort and to prevent death from intestinal obstruction.

The case shows also that ileocolostomy may occasionally lead to troublesome diarrhea. We are of the opinion that exclusion of the proximal colon (ileocolostomy) should be practiced only when the lesion lies somewhere between the cecum and the terminal portion of the transverse colon. When the growth is at the splenic flexure or lower, we are in favor of mobilization of the tumor and sufficient proximal and distal bowel to permit resection with lateral anastomosis without tension. A cecostomy is recommended as a "safety valve," either as a first stage or simultaneous with the resection. Ileosigmoidostomy, when the lesion is at the splenic flexure or lower, may lead to intractable diarrhea owing to the fact that the desiccating influence of the transverse colon has been lost.

CASE 10.—Mrs. M. D., aged 48, white, was admitted to the medical service on Oct. 9, 1922, complaining of pain in the lower quadrant and constipation. The past history showed that she had been subject to moderate constipation all her life. She dated her present illness from an attack of severe knifelike pain in the left lower quadrant one year before admission. She was nauseated, but did not vomit. The stools were not ribbon-like, nor did she pass blood or mucus. Since then, she had had severe attacks of diarrhea lasting a day or two. She had especially severe attacks in November and December, 1921, and moderately severe ones in July and August, 1922. She had lost about 20 pounds (9 Kg.) in weight since the onset of her trouble, and had become progressively weaker. In the past six months, she had had increasing need for cathartics.

*Principal Observations.*—On admission, the temperature was 98.4 F.; the pulse rate, 102, and respirations, 23. The patient was a large woman in a fair state of nutrition. The abdomen was soft and relaxed. In the left lower quadrant there was a tender tumefaction which was immovable, regular and hard; the tenderness increased as the flank was approached. The Wassermann reaction and

urinalysis were negative. There were 7,250 white blood cells and 78 per cent hemoglobin. The stools were negative for occult blood. Roentgen examination showed a definite constriction in the upper sigmoid colon.

Oct. 13, 1922: The patient was advised of her condition, but refused operation and was discharged.

December 8: She was readmitted to the medical service. Since her discharge from the hospital, she had had no relief from her abdominal pain and obstinate constipation. She had had occasional periods of diarrhea followed by severe constipation.

December 10: She was transferred to the surgical service.

*First-Stage Operation.*—Removal of carcinoma of the sigmoid and lateral anastomosis of the colon; preliminary simultaneous colostomy (fig. 11).

December 11: The abdomen was entered through a long left rectus incision. A definite small mass was found in the sigmoid, in keeping with the roentgen observations. The mass was annular, hard and fibrotic, and much smaller than the tumors in the previous cases. There were definite nodules in the posterior retroperitoneal tissues and the mesocolon. Mobilization of the tumor mass was accomplished by digital dissection, and liberal resection of the bowel on either side of the mass was done. A satisfactory lateral anastomosis was accomplished without tension. Just before the anastomosis was accomplished, a small knuckle of cecum was brought through a right McBurney incision. Our purpose was to have a "safety valve" in case of distention and pressure on the line of suture, the colostomy to be completed or not as the exigencies of this case might demand. Two large drains were inserted into the abdomen lateral to the line of the anastomosis.

December 12: The colostomy was established by electrocautery. Gas and fecal matter escaped, and the distention was relieved. Improvement followed quickly.

December 27: The patient made a very satisfactory convalescence. The abdominal wound almost entirely healed.

*Second-Stage Operation.*—December 29: With the patient under gas-oxygen anesthesia, the colostomy was closed. The wound was packed with iodoform gauze (fig. 11).

Jan. 12, 1923: The patient began to have frequent bowel movements. She was out of bed daily for the previous week and was discharged on January 12, entirely relieved from her complaints save for a slight feeling of weakness.

*Subsequent Report.*—Aug. 2, 1925: The patient died. Death was due to progressive cachexia resulting from metastases. No obstructive symptoms appeared at any time.

*Comment.*—This case is the third in our series in which the tumor was palpated, and further emphasizes the necessity for early diagnosis and early surgical intervention if a cure is to be hoped for in carcinoma of the colon. It was more than two years before this patient presented herself for the necessary examinations. In consequence, it was merely possible by operation to relieve the obstruction and prolong her life in comfort. The definite and advanced glandular involvement precluded a cure.

From an operative standpoint, the "safety valve" cecostomy without doubt insured an almost immediate smooth convalescence free from pain,

abdominal discomfort and distention. Furthermore, it prevented leakage with possible peritonitis, fecal fistula or abscess formation by relieving strain and tension on the line of sutures (compare case 5). The surgical closure of the cecostomy did not in any manner interfere with her uneventful convalescence.

CASE 11.—Mrs. B. R., a woman, aged 60, white, was admitted to the hospital on Nov. 3, 1922, complaining of constipation, nausea and colicky abdominal pain. Her past and family histories were irrelevant. For four years previous to admission, she had had vague symptoms due to constipation. She was relieved by laxatives. Colicky pains in the lower part of the abdomen and in the region of the umbilicus had been frequent. Severe nausea and vomiting occurred five days before admission. The vomitus consisted of food that she had recently eaten. She had not had a bowel movement for six days, and could take fluids only. There had been a gradually increasing distention of the abdomen. She complained of weakness, headache and general malaise.

*Principal Observations.*—On admission, the temperature was 99 F.; the pulse rate 85, and respirations, 24. There was a slight generalized abdominal distention with an apparent greater fulness on the right side than on the left. There was no abdominal rigidity or visible peristalsis, although active peristalsis was transmitted to the palpating hand. Definite gurgling was elicited on auscultation above the umbilicus. There was extreme tenderness in both lumbar regions, particularly the right. There were no palpable masses. The stool showed occult blood. The urine was markedly positive for acetone and indican. There were 9,200 white blood cells and 76 per cent hemoglobin.

Nov. 7, 1922: By means of enemas and persistent mild catharsis, the constipation and distention were relieved.

Roentgen examination showed a definite obstruction in the upper sigmoid.

The patient felt greatly relieved from her obstructive symptoms and insisted on going home. She was reluctantly discharged on November 12.

November 17: She was readmitted. Since leaving the hospital on November 17, she enjoyed a short interval of comfort. For three days before operation, she was obstinately constipated in spite of very vigorous catharsis and other measures of relief. She had a constant feeling of nausea during the past three days.

November 19: By means of enemas and mineral oil by mouth, her distention had once more been considerably relieved. She has been persuaded with difficulty to accept surgical treatment.

*First-Stage Operation.*—*Exploratory laparotomy; colostomy.*

November 21: A low incision was made from the umbilicus downward. A very small amount of free straw-colored fluid was noticed. In the upper sigmoid, a soft, yellowish, gelatinous-looking mass about the size of an ordinary lemon was noticed. In close proximity, the colon presented a definite scirrhus annular constriction. The mesocolon was free from any visible or palpable lymph glands. The case seemed to be rather favorable for surgical treatment. A McBurney incision was made. A knuckle of cecum the size of a bantam egg was anchored in the wound in anticipation of cecostomy.

Following the operation, the patient felt quite weak. By means of sodium bicarbonate and dextrose, acetonuria was satisfactorily relieved.

November 23: Two days following operation, cecostomy opening was made by electrocautery. Rapid improvement followed.

*Second-Stage Operation.—Excision of tumor; lateral anastomosis (fig. 11).*

December 6: The tumor was found without difficulty. The proximal colon was now quite normal. A liberal resection, including the entire tumor mass and considerable proximal and distal zones of normal bowel, was accomplished. A lateral anastomosis was made without tension. Two large cigaret drains were inserted to the anastomotic line. The omentum was pulled downward and lateralward so as to obscure and cover the small intestines to guard against spreading infection.

December 8: Following this second operation, convalescence proceeded very satisfactorily.

*Third-Stage Operation.—Closure of colostomy; exploration of tumor of right shin.*

Jan. 5, 1923: With the patient under gas-oxygen anesthesia, the colostomy was closed.

NOTE.—The patient had recently been complaining of pain in the right leg below the knee. Just above the midportion of the tibia anteriorly, an oval rounded tumor was seen and felt. It lay below the subcutaneous tissues. Exploration showed that the tumor was similar in appearance to muscle tissue. The tibia was definitely eroded below the tumor (fig. 6). A specimen of tumor mass was removed for histologic study. Subsequent histologic study showed that the tumor was of an adenocarcinomatous nature (probably metastatic).

January 16: Roentgen examination showed a subperiosteal tumor in the anterior portion of the upper third of the tibia. The diagnosis was probable metastatic tumor of the tibia.

February 15: The patient was gradually getting stronger; the appetite was fair and the bowel movements were free. The operative area over the right tibia was completely healed and less tender following a roentgen exposure.

*Subsequent Report.*—March 28: The patient appeared for examination and roentgen exposure of the metastatic tumor of the tibia. In general, she had gained weight, looked well and was quite optimistic. She complained of slight pain in the tibia. Roentgen examination showed an increase in the extent of the involvement of the tibial tumor, but the upper two thirds of the affected area showed definite bone repair. Roentgen treatments are being continued.

*Comment.*—This case, even more than the preceding cases, illustrates the great necessity for early diagnosis, for it was four years after the onset of her present illness that she was submitted to proper diagnostic measures. In spite of the very evident chronicity in this case, the mass was definitely localized, movable and surprisingly free from local or general adhesions. Also, there were no visible or palpable regional lymph glands. In fact, at the time of operation, it seemed a most favorable case. Our hopes as to permanent cure, however, were definitely dispelled when the metastatic tumor of the right tibia made its appearance. This would indicate that occasionally distant metastases occur in spite of the rather favorable local conditions. The symptomatology in this case was sufficient to have led to a diagnosis long before it was made.

# Summary of Clinical Observations in Ten Cases of Carcinoma

	Date of Admission (Surgical Case Service)	Sex and Age	Diagnosis	Constipation or Diarrhea	Abdominal Pain	White Blood Cells and Hemo globin	Loss of Weight	Weakness and Toxic Symptoms	Distention	Peristalsis
1	12/31/19	M 46	Obstruction of the colon; adenocarcinoma of the hepatic flexure	First noticed three months ago; no diarrhea	For several months; at times colicky	13,000 75%	Marked, 100 lbs in six weeks	Marked weakness and malaise	Extreme distention with intestinal patterns	Visible with griping
2	10/19/20	M 57	Obstruction of the colon; adenocarcinoma of the hepatic flexure	Alternating constipation and diarrhea for past month	Present 1½ years, increasing in severity and duration	9,640 71%	16 lbs	Great weakness, slight vertigo	Never marked	Not visible severe griping
3	10/27/20	M 62	Adenocarcinoma of hepatic flexure; no obstruction	Repeated attacks of diarrhea; rarely constipation	Increasing in severity during past 3 years	7,200 64%	30-40 lbs	Slight weakness, no vertigo or toxic symptoms	Little, if any	Not visible, occasional griping
4	2/3/21	F 32	Obstruction of lower colon; adenocarcinoma	Chronic constipation for 2 years, obstinate for past 2 weeks	For past 1½ years, at times violent and griping	8,400 80%	No loss of weight	None	Very marked	Visible with patterns at times
5	5/7/21	M 45	Obstruction of descending colon; adenocarcinoma	Constipation all his life, no diarrhea	Suddenly 2 days before admission not before	9,600 90%	None, patient well nourished	None	Marked during past two days only	Not apparent
6	12/21/20	F 60	Obstruction of ascending colon; pericolic (vascularized) adhesions	Constipation for past 8 weeks, no diarrhea	Slight pain and discomfort after meals	9,000 80%	24 lbs in two months	Weakness and vertigo when arising	None	Not apparent
7	9/26/21	F 42	Obstruction of the colon; pericolic (vascularized) adhesions	Constipation progressive in past year, diarrhea once	Abdominal distention but no pain	7,800 55%	52 lbs in 11 months	Dizziness and faintness, occasional headache	Only slight at intervals	Not apparent
8	1/19/22	M 64	Obstruction of the descending colon; adenocarcinoma of sigmoid colon with metastases	Constipation and diarrhea 4 years ago and during the past 3 months	Severe cramps during past months	7,200 62%	23 lbs	None	Slight and only during the past week	Marked griping but no visible peristalsis
9	2/5/22	F 64	Obstruction of the colon; adenocarcinoma of the transverse colon with metastases	First noticed 1 year ago, constipation during past 3 months, no diarrhea	Colicky during past year	9,600 78%	Slight, if any	None	Little, if any in past	Griping but no history of visible peristalsis
10	12/10/22	F 42	Obstruction of the colon; adenocarcinoma of the sigmoid	Constipation for past 27 months	Frequent; at times colicky and knifelike	9,000 91%	16 lbs	Slight weakness, otherwise negative	Little, if any	No history of visible peristalsis
11	11/20/22	F 60	Obstruction of the colon; adenocarcinoma of the colon	Progressive constipation, no diarrhea	Severe cramplike in character	9,200 76%	Not known	Weakness, headache and general malaise	Only slight	Peristalsis transmitted to palpating hand
12	2/18/23	F 58	Obstruction of the colon; adenocarcinoma of sigmoid	Progressive constipation, no diarrhea	Not a marked symptom	9,500 90%	50 lbs in 12 months	Marked weakness	Frequently noticed	Peristalsis palpable but not visible

*of the Colon, and Two Cases of Pericolic Membranes*

Blood in Stools	Abdominal Tenderness	Palpable Tumor	Temperature, Pulse Rate, Respirations on Admission	Number and Types of Operations	Complications	Date of Discharge	Late Results
Small hemorrhages for past 5 months	For several months	Negative	98.6 F 85 23	1 Cecostomy, 2 ileocolostomy with resection	Gastric retention, bronchopneumonia	5/25/20	No complaints referable to former disease, last examination on Feb 4, 1923, weight 175 lbs; alive in February, 1923, 5 years after operation; not heard from since
No positive history	Slight in upper quadrant	Negative	100 F 90 25	1 Cecostomy, 2 ileocolostomy, 3 resection	Wound infection	1/12/21	Well at time of examination on Feb 4, 1923; weight 132½ lbs; well in November, 1923, eight years after operation; has resumed his former occupation
No history	None	Negative	98.6 F 85 20	1 Ileocolostomy, 2 resection	Slight bronchitis	12/11/23	Well at examination on Feb 4, 1923; weight 160 lbs; gain of 20 lbs since operation, well in February, 1927, seven years after operation
Negative for occult blood no history	Only slight	Negative	99.6 F 75 25	1 Mikulicz operation	Infection of abdominal wall with abscess local peritonitis and obstruction, death	2/17/21	Died ten days after operation (Mikulicz), infection of abdominal wall and peritonitis
No history	Absent	Negative	99.4 F 110 25	1 Excision of tumor, lateral anastomosis of transverse and descending colon	Wound infection, fecal fistula	7/30/21	Well at examination on June 22, 1923, eight years following operation, weight 200 lbs, gain of approximately 90 lbs since operation, has resumed his former occupation
No history	Not definite	Negative	98.6 F 64 20	1 Release of pericolic adhesions	None	1/10/21	Well at last examination, Feb 4, 1923, two years after operation, (benign lesion), marked gain of weight
No history	None	Negative	98.6 F 64 20	1 Release of pericolic adhesions	None	11/4/21	Well at last examination on Feb 4, 1923, one year and three months after operation (benign lesion)
Four years ago and again during past month	Slight	Palpable	100.2 F 96 22	1 Exploratory laparotomy, colostomy for relief of obstruction	None	3/12/22	Death reported by family physician ten weeks after operation, marked cachexia due to extensive metastases and myocardial insufficiency
No history	Present especially during past 3 months	Large mass palpable	99 F 80 20	1 Ileocolostomy for relief of intestinal obstruction	Diffuse bronchitis	3/12/22	Died six months following operation; extensive liver metastases and myocardial insufficiency
No history	Localized in left lower quadrant	Small irregular mass in left iliac fossa	99.6 F 100 24	1 Resection and lateral anastomosis, simultaneous colostomy; 2 closure of colostomy	No early complication, late generalized metastases	1/16/23	Died on Aug 2, 1925, from extensive metastases; no symptoms of obstruction since operation
No history - occult blood on examination	Severe in both flanks	Negative	99 F 87 24	1 Exploratory laparotomy; preliminary colostomy; 2 excision of tumor, 3 closure of colostomy	Bone metastases	2/15/23	Died of generalized metastases approximately ten months after operation, on March 28, 1923; less than three months following the last operation, appearance of tibial metastasis noticed
From the very beginning	None	Cylindrical mass palpated	98 F 90 20	1 Resection of tumor and lateral anastomosis; simultaneous cecostomy	Surgical shock; local peritonitis, death	2/26/23	Died five days following operation; shock and peritonitis

CASE 12.—Mrs. B. M., aged 58, was admitted to the hospital on Feb. 19, 1922, complaining of lack of appetite, loss of weight, abdominal pain and blood in the stools. The past history was negative. The present illness began one year before examination when the patient began to lose her appetite and complained of weakness. Blood was present in the stools at various intervals in the year previous to admission. She said that she lost 50 pounds (22.7 Kg.). She had to resort to cathartics in increasing amounts. Belching and distention had been frequent. There was pain on straining, but no vomiting.

*Principal Observations.*—The temperature was 98 F.; the pulse rate, 90, and respirations, 23. The patient was an elderly apprehensive, undernourished and pale-looking woman. The mucous membranes were pale. The skin was dry. The abdomen was rounded, soft and flabby. In the left lower quadrant over the brim of the pelvis, a cylindric, movable and slightly tender mass as large as a lemon could be felt. There were 9,500 white blood cells, 5,300,000 red blood cells and 95 per cent hemoglobin. Urine showed a light cloud of albumin and a few hyaline and granular casts. Roentgen examination indicated an obstruction in the first portion of the sigmoid.

*Operation.*—*Resection of carcinomatous mass and lateral anastomosis; simultaneous cecostomy (fig. 11).*

Feb. 21, 1923: An incision was made from the symphysis to a point just above the umbilicus and slightly to the left of the midline. An irregular, firm and slightly movable mass about the size of a small fist was found over the brim of the pelvis. There were no palpable glands in the retroperitoneal tissues. The tumor mass was removed, a lateral anastomosis was made and a small portion of the descending colon just above the cecum was brought out from a right inguinal McBurney incision and held in position by a number of interrupted fine catgut and silk sutures (to be opened later).

February 22: There had been considerable vomiting of thin watery gastric contents. The temperature was 101 F., the pulse rate, 120. There was no distention or marked discomfort.

February 23: The patient's condition was only fair. She was anxious and vomited occasionally. Colostomy was completed by cautery. There was a slight escape of gas.

February 24: The vomiting continued. The patient looked dehydrated. There was no frank drainage from the colostomy. Eight hundred cubic centimeters of physiologic solution of sodium chloride was administered in the morning.

February 26: The temperature and pulse rate continued to rise. Vomiting continued. The temperature rose to 106 F., and the pulse rate to 150. The patient died at 2:30 p. m.

*Gross Pathologic Report.*—The excised tumor was a typical adenocarcinoma. The mucous membrane and wall above the tumor were very much thickened. There were no gross metastatic nodules. Several of the glands in proximity looked suspicious. The lumen of the constricted portion of the bowel hardly admitted the finger tip. The center of the growth showed a healed perforation. The wall of the bowel was entirely destroyed in its midportion due to central ulceration.

*Comment.*—This case is interesting in that it is the first case in our series in which the presence of blood in the stools was an early and prominent symptom. It is the fourth case in which the mass was definitely felt before operation. Like the preceding ones, this case also

illustrates the necessity for early diagnosis. The patient was examined fully a year after the onset of symptoms. It was the first case in our series in which radical excision and lateral anastomosis in the presence of a simultaneous colostomy, all in a single stage, was done. The limit of the patient's operative tolerance was evidently misjudged. In a similar case, we would now perform exploratory laparotomy with a preliminary cecostomy as the first stage to be followed by excision of the growth and lateral anastomosis as the second stage. Closure of the cecostomy might even be left for a third stage. By a more liberal application of the principles of the stage operations, this patient would probably have escaped an operative death.

# THE TIME ELEMENT IN QUANTITATIVE PERIMETRY

CLIFFORD B. WALKER

Among the more important reasons for the retarded development of quantitative perimetry since the first principles were laid before the Tenth International Medical Congress by Bjerrum,<sup>1</sup> more than a third of a century ago, is the examinalional time element. Twenty years slipped by before the work of Roenne<sup>2</sup> brought the subject really to the front, and still another ten years before enough material was assembled for such a book as Peters has presented on the subject, or as appears in Traquair's splendid "Introduction to Clinical Perimetry."<sup>3</sup>

It was not so clear to me that the time element was the real essence of the backwardness of the subject until about three or four years ago when I asked the chiefs of some of the larger clinics, as for instance, the Mayo Clinic, why the old method of perimetry was still used when the new quantitative method was known to them. The answer was that the additional time required was prohibitive. It seemed then that time given to ordinary perimetry should be cut in half, or less, if necessary, while one-half or more should be given to quantitative perimetry, and no great advance in the subject could be expected until this attitude was taken very generally in the larger clinics.

In the last two or three years interest in quantitative perimetry has increased greatly, so that now the situation is such that with some careful simplification and time-saving devices, one may hope to see it come into the same general use, even greater use, than ordinary perimetry has enjoyed. Later, as fast as familiarity with the subject has extended to students and interns, those who are especially interested will naturally add more refinements and time to the examinations. How this was attempted in a good sized clinic, that of the Los Angeles General Hospital, will be described here in the hope of stimulating further interest.

As a matter of fact, readings can be made and recorded much faster on a screen than on the ordinary perimeter for the simple reason that time is not lost in setting an arc for each reading, and that direct marking on a screen can be made more rapidly and accurately than direct or automatic marking can be with the various perimeters.

2. Roenne: Zur Theorie und Technik der Bjerrumschen Gesichtsfelduntersuchung. Arch. f. Augenh., 1915, vol. 78.

3. Traquair: Introduction to Clinical Perimetry. London, Henry Kimpton, 1927.

The origin of the idea that screen work is more difficult or time-consuming can be traced to the thought that screen work requires the use of tangent scales, mathematics and special charts, and it is in this morass that time is mentally lost in preliminary cogitations when an outfit is not made, and actually lost when the attempt is really made to do quantitative work. In other words, it seems as if the fear of inaccuracy has been another stumbling block, and that the ophthalmologist feels that if he cannot take mathematically accurate measurement on the screen, he will not bother with it, believing that the time to get such a result is excessive compared with other examinations.

At the outset this inhibitive idea, conscious or subconscious, should be combated by the facts that (1) the pattern or picture presented by a screen or perimetric test is of greatest importance, and this can be obtained from a screen or perimeter even if it is not marked quite accurately; (2) while it is well to have accurate measurements, the subjective inaccuracies (personal equation) of the patient, as well as of the observer, will always be links of sufficient weakness to override the ordinary inaccuracies of a technical nature, especially when simplified to the extent proposed in the following description:

From the mass of elaborations of the pathfinders in any subject, simple rules are later taken for routine work. On reviewing the fundamental facts for simplifying shortcuts, one finds that nature lends assistance. Thus while the errors and distortions of the tangent screen multiply rapidly beyond 25 degrees from the center, yet the normal field extent contracts rapidly as the size of the visual angle of the test object decreases so that when 1.7 minutes is reached, a circular field of about 26 degrees extent is obtained, and within this threshold are found the most important and informative isopters in early cases.

This field condition is obtained with the 1 mm. disk at 2,000 mm., on a screen about 2 meters or 80 inches square. This screen and test object give the most efficient conditions for general use, although if the width is made greater, up to 100 inches, it is still better in some ways. The visual angle is then small enough to make a searching test of the most important region of the field, that is, the paramacular and perimacular region and the cecal or blind spot region. It will show all the important signs such as Bjerrum's scotoma, Seidel's scotoma and Roenne's nasal step, and will be sensitive to other peripheral weaknesses. Still the tangential error of the screen does not much exceed 1 degree in the neighborhood of the 20 degree circle on the screen. This distance (2,000 mm.) makes it easy to examine persons with presbyopia and those who wear glasses for distance, except that the bifocal addition must be avoided. As regards the test objects for this distance, the 1 and 2 mm. disks will fill the major part of the requirements.

To conserve time, then, one should keep in mind while assembling the outfit that the 30 degree screen at 2 meters has the most general efficiency, and that for the present one must be willing to sacrifice a little accuracy for speed in developing the somewhat more important pattern of the field defect.

The room should be well lighted; if it is invaded by direct sunlight, ordinary translucent thin white curtains should be available, and for cloudy days or night work, two or three 200 watt lamps just back of the patient on both sides and perhaps one above the patient's head will give results practically equal to daylight in a room which should measure at least 15 feet in front of the screen. A north light under these conditions is not essential.

While it is possible to do considerable perimetry in a noisy clinic, and it might be considered better than no perimetry, nevertheless every effort should be used either to get a special room or to examine patients at the quietest clinic hours.

The screen should be at least 80 inches wide horizontally; 100 inches wide is better. It should be 80 inches vertically. It is difficult to get goods 80 inches wide in some department stores, and if goods only from 54 to 72 inches in width is obtainable, it is better to form a seam to extend across the top and bottom rather than allow any seams in the central region. The material should be dull black without gloss, but with a felt like finish, and without long nap. A true felt offers an ideal surface but is apt to stretch unevenly and give a warped surface after a time.

This sort of screen may be supported either in a movable frame having a floor pedestal as a wall map on a curtain-roller, or on an overhead wire. However, in order to obtain the use of both sides of the screen, for reasons later to be described, a three point wall suspension on two rods, three hooks and variable lengths of chain is used. The three-eighth inch solid brass rods are slipped through the full length of 1 inch hems in the upper and lower margins of the screen. The weight of the lower rod holds the cloth straight and taut, while the stiffness of the upper rod is sufficient to give a straight border when it is supported by three rings which pierce the goods at both ends and at the center. From these three rings, chains or strings may be used to extend up a variable distance of a foot or less to corresponding hooks, thus making it possible to bring the center of the curtain on a level with the patient's eyes. The center point of support also has a stout cord extending up to a ceiling hook, so that when it is desired to reserve the curtain for certain examinations, the three supporting hooks are released, and the screen suspended by the cord only swings forward from the hook in the ceiling about 2 feet in front of the wall position of the screen. The screen is then easily turned on its vertical axes

through 180 degrees (reversed) and replaced on the wall hooks. The object of this arrangement is to obtain, without departing from simplicity, a range of use from 1,000 to 4,000 mm., although the 2,000 mm. distance will be used by far the largest part of the time. The center of the screen, the fixation point, will average 40 inches or a little over a meter from the floor, and can usually be arranged to be at the exact center of such a screen as I have described.

Ordinary light colored surgical adhesive cut in various sizes may be stuck on the center of the screen as fixation points. Pieces from 5 to 10 mm. square are usually satisfactory. For routine work, the square fixation spots are used because they are a little easier to make and place on the screen, and because they are easily referred to in contradistinction to the circular test objects. But other shapes to suit the requirement are quickly made. For instance, a black central portion can be made by cutting out the center of the adhesive making a hollow square or doughnut shape. Or by making two narrow strips pointing to and reaching almost to the center along the vertical line or slanting toward the seeing field, such things as sparing of the macula and relative central scotomas are easily studied. Also rather large deeper gray adhesive with or without a hole in the center may be used for small central scotoma. Then smaller and brighter test objects may give readings right over the fixation spot as if it were not there. The use of two or more spots at the margins of a central scotoma may be helpful in case of larger central scotomas in both eyes. Of course, if central vision is good in one eye only, a special study can be made with the stereo campimeter as a substitute for the perimeter work, and a form of macular selection can be used in screen work, though the proper form of fixation object will usually suffice.

Perhaps the easiest way to mark a screen for ordinary work is to sew a little knot of black thread on the surface without going through the goods at the intersection of each 30 degrees meridian with each 10 degree circle. It is hardly necessary in order to stay within the limits of accuracy to trace the entire length of meridian and circle with thread sewing, although this can be done. For instance, in the last screen made for Dr. Lyster's clinic at the Good Samaritan Hospital, I had the meridians sewed through the goods with black thread since these markings are the same on both sides of the screen. Then a small electric soldering iron at the lead melting temperature was used to mark the various circles not solidly but by short (1") dashes on each side of all crossings. The center, vertical and horizontal limits of each blind spot location was also indicated by small cross marks. These permanent markings are a great help to those who do screen work only occasionally. The suspension was also different in that the height was regulated by having a series of wall hooks 2 inches

apart vertically in three rows. This arrangement permitted of easier reversing of the curtain by simply bringing the bottom rod up to the top and the top down to the bottom. In order to locate the intersecting points previously mentioned, the meridian and circles are plotted on the screen with chalk, wax crayons, or tailors' soapstone. Of these, I prefer the wax or paraffin crayons because their streak is so cleanly removed with the slightest rub from a bit of gauze moistened with carbon tetrachloride or "carbona" cleaning fluid. The curtain is thereby kept bright and clean, whereas chalk or soapstone will require considerable rubbing and still give some smudge, especially with repeated use. When taking a field, I think the use of dozens of black headed pins is slower and less interesting than the stroke of a dark or barely perceptible wax crayon whose streak can be removed from the curtain just as fast as it can be put on. Then again when contour lines cross at acute angles on the screen in the course of an examination, it is much easier and more accurate to record with the crayon than with a multitude of black pins. Occasionally a small black headed pin is overlooked and left in the screen, perhaps leading to confusion or error in later examinations. But it is not burdensome to have both methods available and use either one or both in different stages of the same examination if it seems to aid in accelerating the work.

For routine clinical work, when it is often necessary to remove every possible hindrance to perimetry of a mathematical or technical nature, especially when it will often and perhaps usually be necessary for clinicians to construct the screen, if one could discard the use of tangent tables, which seem never at hand when needed in a hurry, and simply use 10, 20, 30 degrees, etc., of the arc of the circle with radius equal to the distance from screen to patient as the radius for the corresponding circles on the screen, calculations would be very simple indeed. That it is really within the limits of accuracy to do this rather than add the complications of warped surfaces or tangent tables can be shown by use of some calculations previously published.<sup>4</sup> Thus by reference to table 1, it will be seen that the error due to increase of distance from the patient's eye of the test object between 25 and 30 degrees from the fixation point results in a diminishing error of from  $1\frac{1}{2}$  to  $3\frac{1}{3}$  degrees, that is, the readings are too small by that amount due to the smaller visual angle. Now again by referring to table 2 for the same region on the 2,000 mm. screen, it will be seen that the difference between tangent circle and arc circle varies from 6 to 10 cm., which in terms of degrees means from 2 to 3 degrees, and this is of an increasing nature with regard to field readings, that is, the arc

---

4. Walker, C. B.: Quantitative Perimetry: Practical Devices and Errors. *Arch. Ophth.* 46:537, 1917.

measurement is smaller by from 2 to 3 degrees in this region than the tangent measurements.<sup>5</sup> It seems clear, then, since one can substitute the arc for the tangent and stay well within the limits of accuracy, about 1 degree, by using the simplest method of marking the screen. This will hold true out to about 35 degrees, but beyond 40 degrees the resulting error becomes greater than 2 degrees and the screen is not recommended beyond that point, but rather a reduction of visual angle either by increasing distance or by decreasing the size of the test object to obtain a smaller field is advisable.

The screen is marked permanently on one side for a distance of 2,000 mm. and on the other side for 1,500 mm. since by the foregoing system of using the arc instead of the tangent measurement, the marking for 2,000 mm. can be used also for 1,000 and 4,000 mm. in this way: When a distance of 1,000 is used, the 10 degree mark for the 2,000 mm. scale becomes the 20 degree mark for the 1,000 mm. distance, and also the 5 degree mark for the 4,000 mm. distance. Likewise, the 20 degree circle at the 2,000 mm. distance becomes the 40 degree circle when used at 1,000 mm. and also is the 10 degree circle when used at 4,000 mm. These simple relations are easy to remember in transferring measurements from the screen to the chart. The side carrying the marking for 1,500 mm. is likewise readily used at 750 and 3,000 mm. This range of six distances from one piece of goods is of advantage when rapidly testing for neurasthenia, hysteria and disproportion in response to size of color disks relative to size of white disks as will be discussed later.

If one should have the full list of test objects that various observers have used or that might be useful, ranging from 1 to 70 mm. in diameter in white, red, blue and green, upward of forty disks would be used. It think before long there will be sufficient demand for disk sets that some manufacturer will supply them as disks on the flattened head of dull black pins, which may be renewed when soiled, in the ends of long slender dull black handles. But at present when one must keep the white and colored test objects clean as long as possible, the knife edge rim which I suggested in 1913<sup>6</sup> will prevent soiling for months and in some cases for years. At present, Bausch and Lomb Co., and Meyrowitz Co., are the only companies making these disks.

Without doubt the 1 mm. disk may be considered the most indispensable since it is used oftener. It should be the most accurately made since a plus or minus error of one tenth of 1 mm. in this disk

---

5. This result is obtained by use of a plot of the variation of field extent with reference to visual angle of the test object.

may result in errors of from 4 to 12 degrees at various distances (table 3).<sup>4</sup> Much variation can be made in the rest of the set. The 2 mm. disk is perhaps the next most commonly used, then the 5 mm., the 10 mm., the 20 mm. With a set as small as this, much important work can be done. If a further addition is made to the set, select 3, 6 and 50 mm. disks. Having gone as far as this, a complete set is the next step. The 4 mm. disk is rarely used.

TABLE 3.—*Errors that May Result from a Plus or Minus Error of 0.1 mm. in the Diameter of the 1 mm. Disk*

Distance	Visual Angle of 1 Mm. Disk	Visual Angle Error of 0.1 Mm. in Disk	Visual Angle Corresponding to 0.9, 1 and 1.1 Mm. in Disks	Nasal and Temporal Field Corresponding to Foregoing Visual Angle	Maximum Error Nasally	Maximum Error Temporally

			1.14'	2.3°		
			-1.025'	0.5°		

I have tried disks below 1 mm. in size, but consider them of no great advantage unless a screen and distance is not available. For numerous reasons these tiny disks cannot be made to do screen work on the perimeter. They are difficult to make accurately and magnification of field, necessary for good scotometry, is absent. Errors of refraction are more contributory to error, soiling and breaking is frequent and they run into small awkward decimal numbers, and change of material resulting in a different light reflex is necessary. Small awkward or odd numbers seem to be a handicap to clinical perimetry.

Even numbers easily readable and recordable certainly tend to have a very winning way with ophthalmologists, and more progress will be made if this tendency is followed wherever possible. This factor alone I believe will tend to settle the now quite variable perimetric distance at 300 mm. or 12 inches as used by Roenne, although Traquair, and Ferree and Rand use 330 mm. evidently because it is almost  $1/6$  of the screen distance of 2,000 so that  $6/2,000$  gives almost the same visual angle on the screen as  $1/330$  on the perimeter. This transition from perimeter to screen is of considerable importance in studying certain conditions, for instance neurasthenia and hysteria. But with the screen I have described, one may turn it to the side marked for 1,500 and 3,000 mm. which when used with the perimetric distance of 330 mm. gives the following exactly equal visual angles as represented by simple numbers, thus:  $1/300 = 5/1,500 = 10/3,000 = 20/6,000$ .

The same exactness with 330 mm. perimeter gives:

$$1/300 = 3.03/1,000 = 6.06/2,000 = 12.12/4,000.$$

However, the number of cases in which this transition is made is sufficiently limited so that I believe the 12 inch or 300 mm. perimeter will gradually become the choice because simple numbers contribute to rapid work. Yet one can easily make the perimetric chin rest adjustable for both distances, since only that portion of the perimeter within 30 degrees of the center is used and no change of arc curvature will be necessary; simply make scratches or notches to make the necessary correction of the degree marks out to 30 or 40 degrees, thus having two scales. This will be confusing to some, however, and the 300 mm. perimeter will doubtless be the more popular eventually.

Standardization of charts as well as perimeter and screen calibration, although extremely desirable, will doubtless be difficult to accomplish for some time. Certain features, however, will become more generally notable. As screen work becomes more commonly used, the patients will be examined earlier and earlier in the course of the disturbance until many patients will be found with only one eye affected, and single charts or double charts which may be easily cut into single charts will be made available for either eye, somewhat as Traquair has arranged his charts. Duplication will doubtless be considered. This can be readily accomplished by using a Chinese bond paper which withstands severe usage and is transparent enough to trace duplicate by hand, or by printing on sensitive paper directly as I have shown in a previous paper.<sup>4</sup>

Probably for the same reason that single charts will become more numerous, so also special scotoma charts 30 degrees and less, even to 1 degree in extent but to a correspondingly larger scale than the ordinary chart, will be readily obtainable. These charts will be necessary as

earlier cases are detected more frequently. The double scale necessary for ordinary work on perimeter and screen may be made either by using two sets of numbers at the intersections of circles and meridian as Traquair has done, or by enlarging the central portion of the field as I have done.<sup>4</sup> But finally, I believe results will justify the use of three differently calculated charts for perimeter, screen and scotoma work, for the simple reason that too many readings on one chart lead to confusion, inaccuracies and loss of time both in the making and in the reading.

But, of course, the matter of just the proper chart must not be allowed to prevent making a record because it takes only a few seconds to strike out the numbers on any chart and write on numbers to represent the scale desired. If the blind spot is printed on the chart, it is always easy to erase from good paper with either pen-knife or moist rubber eraser. This possibility of changing the scale of the chart is easily overlooked by those who are not far advanced in perimetry because of the mass of other details to be attended to in the usually limited time.

Perhaps it may be well to illustrate with a case report the manner in which some of those devices are used such as using the same visual angle at different distance, as well as different visual angles at the same distance; using a change of chart scale also if it is desired makes the record show to advantage.

#### CASE REPORT

Mr. G. H., aged 40, referred by Dr. G. H. Hunter from Dr. Cade for the State of California Compensation Insurance Board, complained that everything appeared very much too small and far away. While on construction work a little over a year before examination, he was struck on the right side of the head by a slowly moving timber. He was rendered unconscious by concussion for three hours, but on recovery had no neurologic symptoms or incapacity other than the complaint concerning the vision. One fact in the past history that was not obtained until after several examinations was the occurrence of a period (one and a half days) of total amurosis two years before, during a time of mental stress following an automobile accident from which no injury resulted.

Examination from a general neurologic standpoint was found to be entirely negative before the present reference. The roentgenograms were negative.

Ophthalmologic examination showed that the fundi of the eyes were normal; that in the right eye the optic cup was wider and deeper, showing a larger area of lamina cribrosa. There was no atrophy as suggested by the appearance of the optic nerve head. Refraction of the eyes showed: vision in the right eye, 20/100 + 1 diopter sphere + 0.5 diopter cylinder axis 90 degrees = 20/40; vision in the left eye, 20/70 + 1 diopter sphere = 20/20. The muscular balance was practically normal with both the Maddox rod and the Stephens phorometer.

Color vision was not admitted with either eye. A difference of intensity only was admitted, such as lighter or darker in a photographic sense, and the patient

was successful in eluding traps for malingering on this point, in all the various offices where he had been examined.

In testing the field on the perimeter with 1/300 disk, results were quite variable, but if one proceeded slowly and recorded average result allowing some rest when the patient complained of fatigue, a more or less circular field was obtained as shown in figure 1. The blind spot could at times be outlined in the right eye with an uncertain outer border, while at other times, perhaps when fatigued, there was only an indentation to represent it as recorded on the chart for the left eye. A spiral field could also be obtained on the perimeter though this was easier to demonstrate on the screen where more rapid work is possible.

But mainly it is to be noted that although the visual angle is the same, being 5/1,500, the field is consistently smaller and practically of the same characteristics and size when 20/1,500, giving a visual angle four times as great, is used. With an organic lesion the field taken with the same visual angle on both perimeter and

Fig. 1.—Hysterical type of field, showing gun-barrel contraction, disproportion to same visual angle on perimeter, on screen and spiral fatigue tendency without response to disk size (steep edges) on screen.

screen will be practically the same, and a generally contracted field will not have such steep margins when the visual angle of the test object is increased; i. e., more response to disk size would be expected in nonhysterical patients. The patient was open to suggestion to a considerable extent if he could be convinced that it would not prejudice his case. Thus at first he contended that all objects were reduced to one-fourth their normal size. Yet his central vision was very good. Later, while he contended some diminution was present, the ratio was gradually raised to three-fourths.

While this case may be of some interest in showing evidence of hysteria with some fatigue symptoms of neurasthenia, the chart can be used still further to bring up some technical points: (1) the manner

of charting the record, and (2) showing the appearance with change of scale using the same chart.

As regards the first point, it is notable that most perimetrists including Bjerrum,<sup>1</sup> Roenne,<sup>2</sup> Traquair<sup>7</sup> and Sinclair,<sup>8</sup> use smoothly curving lines to indicate the contours or isopters for the various test objects, and no points or dots indicating definite readings are used. Others, considerably in the minority, propose to have each measurement recorded by a dot of diameter perhaps two or three times the width of the connecting lines which are made straight from dot to dot and therefore are not designed to approximate the probable field contour but merely diagrammatically to connect the known points. The latter method often results in neater appearing records since short straight lines are

Fig. 2.—Same field as in figure 1, magnified by change of scale 2; 1 in right eye and 3 to 1 in left eye.

easier for the average person to draw than long smooth curves, while the presence of large black dots seemed almost an affidavit to the fact that readings were certainly taken at those points. Since this method is a little more prevalent among neurologists and those who are forced often to delegate the work to assistants and interns, it seems as if it was a method of stimulating greater care on the part of the workers and a chance for a check up on the part of the chief. At any rate, I well remember with what telling effect "our Chief," Harvey Cushing,

7. Traquair, H. M.: The Quantitative Method in Perimetry, with Notes on Perimetric Apparatus, *Ophth. Rev.*, March, 1914, p. 65.

8. Sinclair, A. H. H.: Bjerrum's Method of Testing the Field of Vision, the Advantages of the Method in Clinical Work, and Its Special Value in the Diagnosis of Glaucoma, *Tr. Ophth. Soc. U. Kingdom*, 1905, p. 384.

used on occasion to recount a case in the early days when the hurried intern had stretched the interval of his readings a little and thereby missed a narrow deep notch close to the upper midline. If this had been found, a diagnosis of tumor of the brain could have been easily made at once, while as it was, Dr. Adolph Meyer had to study the case long and hard before suggesting a "retake" of the field with especial reference to the quadrants where the field defect was later found, thereby demonstrating nicely the significance of what is now referred to as Meyer's loop, in the optic radiation.

For that period of perimetry when the larger lesions of the field were being detected with 0.5 cm. disks, usually one white and three colored disks, every measurement could be recorded with large dots, but later when the refinements of screen work began to be added the dots, while still used, began to clutter up the field when the number of readings increased greatly within the small areas (20 degrees) around the blind spot and macula, so that I do not expect to see their use increase from now on, but rather the reverse. This will certainly be true in scotometry; otherwise the field when recorded as actually taken will occasionally look like a little string of beads.

This beading in the central region can be avoided considerably by changing of the scale on the chart, which brings one to a second point as illustrated by figure 2, showing the same field as figure 1 with the scale magnified from 3 to 1 for the right eye and 2 to 1 for the left eye as compared with the usual scale as used in figure 1. The blind spot of the regular chart is simply erased and the new scale numbers marked in larger size at the proper intersections. The transfer from one scale to another can then be accomplished with practically the same degree of accuracy as in the first place from screen to the chart.

#### CONCLUSION

1. Screen work may be simplified and time saved without sacrificing any necessary accuracy by using degrees of arc rather than tangent measurements to offset the natural screen errors outside of 20 degrees to increasing distance.

2. When this is done the same markings can be used for 1, 2 and 4 meters distance on one side of the screen and the other side of the screen can be similarly marked for 1.5 and 3 meters to stand in exact simple multiple relation to a 300 mm. perimeter.

3. Under these conditions, the disk series falls also into simple multiples of whole numbers.

4. The use of dark wax crayons to mark on the screen permits more rapid recording on the screen during examination, and easy removal afterward with carbon tetrachloride.

# SOME LIMITATIONS OF THE MONRO-KELLIE HYPOTHESIS \*

LEWIS H. WEED

For almost a century and a half, the hypothesis that the skull and bony coverings of the vertebral canal form a rigid container for the central nervous system has occupied the attention of anatomists, physiologists and neurologists. It is a hypothesis which has been gradually changed in its scope, and even in its conception, since its original promulgation by Alexander Monro<sup>1</sup> in 1783. Having been of interest to many in the course of the first fifty years of its existence, the doctrine has, in the past three decades, again become the subject of intensive investigation by workers in intracranial physiology. It is a tenet which has particularly concerned neurologic surgeons, because on its truth, or relative untruth, depend many of the critical procedures in the surgery of the central nervous system. The doctrine has especially intrigued the scientific curiosity of Harvey Cushing, to whom the academic world owes a vivid presentation of this hypothesis<sup>2</sup> that the contents of the cranium are at all times relatively fixed in volume, and that variation in any of its three constituent elements must be compensated by reciprocal variation in the quantity of one or both the other elements. It is the purpose of this article to assemble anew the various fractions of evidence which underlie current belief in the truth of the doctrine, presenting, in part, work already published by me and detailing new observations which widen the field of knowledge of the limitations of the hypothesis.

As one superficially examines the bony skeleton, particularly of man or of other higher vertebrates, one is impressed by the tremendous gaps in the bony structures constituting the vertebral column and the bony skull. Were one's knowledge of anatomy confined to skeletal remains, one would have difficulty in conceiving the skeleton to be an effective covering for the central nervous system. But as one's anatomic knowledge advances, one realizes that the many foramina in the skull are closed by the tough and inelastic dura mater, which intimately invests all the entering and emerging structures. In the vertebral canal, somewhat similarly, the intersegmental ligaments form

---

an almost equally tough, though slightly elastic, bridging mechanism, so that the vertebral tube forms a complete bony and fibrous investment, perforated segmentally by nerves and blood vessels. With the *dura mater cerebri* closely applied to the inner surface of the skull, the cranial box may easily be considered an intact container for the brain, but in the spinal cord, with the *epidural* space filled (in the mammals) with a fatty areolar tissue and a plexus of thin walled veins, the analogies seem distant; for between the *dura mater* and the inner fibrous lining of the vertebral canal, the amount of inelastic fibrous tissue is small, indeed, and this bridging tissue seems hardly capable of maintaining the spinal *dura* in its proper position of distention. Excluding the points of emergence and entrance of the spinal nerves, the fibrous coverings of the spinal cord surely may be considered to lack rigidity in one particular region—that of the occipito-atlantoid ligament. For here, as has been known for a century, pulsations of the intradural fluid contents may be seen under favorable conditions during the life of an animal.

#### LITERATURE

Such thorough and detailed anatomic conceptions could hardly have been appreciated by Alexander *Monro*,<sup>1</sup> when, at the end of the eighteenth century, this celebrated Scotch anatomist turned his attention to the problems of intracranial physiology, and devoted to this subject a few of the pages of his epochal monograph "The Structure and Functions of the Nervous System." Here one finds for the first time in scientific literature the hypothesis that the blood circulating within the cranium must at all times be constant in volume. *Monro's* own words give a comprehensive idea of his method of reasoning: "as the substance of the brain, like that of the other solids of our body, is nearly incompressible, the quantity of blood within the head must be the same, or very nearly the same, at all times, whether in health or disease, in life or after death, those cases only excepted, in which water or other matter is effused or secreted from the blood-vessels; for in these, a quantity of blood, equal in bulk to the effused matter, will be pressed out of the cranium."<sup>3</sup>

The primary basis for this hypothesis was *Monro's* anatomic generalization that the brain is "enclosed in a case of bone";<sup>3</sup> and it followed quite logically that within a rigid container, such as the cranium, the contents must at all times be of the same volume. Holding the brain to be incompressible and being cognizant of the existence of but one fluid element within the skull-case, *Monro* assumed that the quantity of blood could vary in volume only between the venous and the arterial sides.

3. *Monro* (footnote 1, p. 5).

Monro's original hypothesis was further developed by George Kellie,<sup>4</sup> whose stimulating report is given in the first volume of the *Transactions of the Medical and Chirurgical Society of Edinburgh* in 1824. Kellie attempted experimental and pathologic verification of the views advanced by Monro. His conclusions, based on observations in animals and in persons frozen to death, were that a state of bloodlessness did not exist in the brains of animals killed by bleeding, that the amount of blood in the cerebral veins was not affected by posture or by gravitation, that congestion of these vessels (particularly on the venous side) was not found in those conditions in which it might well be expected (hanging, etc.) and that compensatory readjustments between the arterial and the venous sides always maintained a constant intracranial vascular volume. Kellie wrote: "That in the ordinary state of these parts we can not lessen, to any extent, the quantity of blood within the cranium, by arteriotomy or venesection; whereas if the skull of an animal be trephined then hemorrhage will leave very little blood in the brain."

With Kellie's apparent verification of Monro's hypothesis, other workers applied the doctrine to pathologic conditions in man, particularly in cases of apoplexy. In these studies, an attempt was made to determine whether the hemorrhage was compensated for by decrease in the volume of the intracranial arterial and venous bloods. The thesis, which quite properly became known as the "Monro-Kellie doctrine," was widely accepted, and interest in it was profound.

Even though the cerebrospinal fluid had been discovered some years before Monro's publication, and even though Haller<sup>5</sup> had given an accurate, though incomplete, account of this fluid filling and surrounding the central nervous system, Monro was apparently in ignorance of its existence. It was only with Magendie's first adequate description<sup>6</sup> in 1825 and with his second more comprehensive monograph<sup>7</sup> on the subject, that knowledge of the cerebrospinal fluid began to spread beyond Europe. Burrows,<sup>8</sup> in 1846, questioned for the first time the thorough accuracy of the doctrine of fixed intracranial blood volume and introduced into the conception the relationship of the cerebrospinal fluid. Burrows repeated many of Kellie's supposedly critical experiments relating to the effect of posture on the quantity of intracranial

blood, and in his colored plates is shown an apparent difference between the intracranial blood volumes of animals, suspended post mortem by the head or by the tail.

Burrows placed great importance on the cerebrospinal fluid as the means of replacing blood lost through systemic hemorrhage, for he felt that exsanguination unquestionably diminished the quantity of intracranial blood. Burrows was somewhat indefinite regarding the possible mechanism for such intracranial readjustments as are necessitated by variations in the volume of cerebral blood. He was unable to decide whether the vacated space under such conditions was filled with serum (cerebrospinal fluid?) or was eliminated by "resiliency of the cerebral substance under diminished pressure"; but in this expression of doubt is contained the first suggestion that the volume of the brain may be altered in accord with physiologic conditions. Summing up Burrow's contentions, one finds that he was in general accord with the major thesis that the intracranial volume is at all times fairly constant—a thesis which necessarily accepts the view that the bony containers of the central nervous system are rigid, preventing alteration in the total volume of the tissues and fluids included within them.

After the publication of Burrow's small volume on this subject, hardly a score of years elapsed before other attempts were made to ascertain the truth of the important hypothesis by experimental methods. Donders,<sup>9</sup> and Kussmaul and Tenner,<sup>10</sup> attempted by direct observations through a cranial window, to secure evidence regarding the constancy or variability of the intracranial vascular volume; their methods, more reliable than observations on dead animals, did not permit control of all the factors. The data presented by these workers hardly justified their conclusion of a variable intracranial blood volume. Many years later (1896), Hill,<sup>11</sup> introducing more rigid methods of physiologic control, concluded that "the volume of the blood in the brain is in all physiological conditions but slightly variable."<sup>12</sup> But under these experimental conditions, either by direct observations as attempted by the earlier investigators or by deductions based on measurement of intracranial pressures (arterial, venous and cerebrospinal fluid), many factors of necessary control could not be given due weight.

12. Hill (footnote 11, p. 77).

Dixon and Halliburton<sup>13</sup> studied the general problem of the Monro-Kellie doctrine in a way but slightly different from that employed by Hill. Basing their conclusions on the apparently great variations in intracranial pressures, particularly in the relation of the cerebrospinal fluid pressure to that in the torcular herophili, they asserted that "the cranial contents cannot any longer be regarded as a fixed quantity without the power of expanding or contracting in volume."<sup>14</sup> Such an assertion necessarily involved extreme modification of the doctrine, if not definite renunciation. The observations of Dixon and Halliburton indicated that unquestionably, within the physiologic limits established, variations in the pressures of cerebrospinal fluid and of cerebral venous blood could be effected without the exact correspondence in pressure relationships given by Leonard Hill.

#### PERSONAL OBSERVATIONS

During the course of investigations to determine what agents, if any, would affect the volume of the brain, McKibben and I<sup>15</sup> ascertained that the intravenous injection of solutions, the osmotic pressure of which differed from that of the blood, caused in the living animal marked alteration in the volume of the brain. It was shown that the intravenous injection of hypotonic solutions markedly raised the pressure of the cerebrospinal fluid and increased the volume of the brain, while the intravenous injection of hypertonic solutions caused lowering of the pressure of the cerebrospinal fluid and corresponding diminution in the volume of the brain. With the intravenous injection of strongly hypertonic solutions, the pressure of the cerebrospinal fluid was frequently reduced to negative values, so that occasionally negative records of as great magnitude as the previous positive readings were obtained in the pressure of the cerebrospinal fluid.

These observations in the living animal caused general reconsideration of the Monro-Kellie doctrine, as the hypothesis of a rigid container for the nervous system formed a fundamental basis of interpretation. It was apparent that these alterations in the cerebral volume and in the pressure of the cerebrospinal fluid, effected by the intravenous injection of solutions of various concentrations, were dependent on the interchange of water and salts between blood and the nervous system with its fluids. But the negative pressures in the cerebrospinal

fluid involved even more the consideration of the accuracy of the *Monro-Kellie* thesis. It seemed quite impossible to obtain a negative pressure in the cerebrospinal fluid unless the bony containers of the central nervous system served as a rigid mechanism, preventing the direct application of atmospheric pressure to the intracranial contents. Under these circumstances, it became desirable to reconsider all the variables in the hypothesis, and to test the conclusion that none of the elements completely filling this rigid container was constant in volume. The total volume of the three elements—blood, cerebrospinal fluid and brain—was looked on as relatively constant. But with realization of the possibility of experimental alteration in brain volume, it was essential to hold that perhaps under conditions of physiologic life, the volume of the brain itself would vary. Likewise, every evidence at hand indicated that the quantity of the intracranial blood would not be constant; and surely there were data enough to lead one to believe that the amount of cerebrospinal fluid would vary. These factors and these assumptions led McKibben and me to the general conclusion that the intracranial contents were at all times of a relatively fixed volume and that the cranial cavity and spinal dural tube were completely filled with blood, cerebrospinal fluid and nervous tissue; that variations in the quantity of any one of these three elements might occur, but that these variations were immediately compensated for by reciprocal changes in the volume of one or both of the remaining elements.

Realizing that this general, though modified, acceptance of the *Monro-Kellie* hypothesis was in many ways based on speculation, and that belief in the general truth of the doctrine depended almost entirely on the interpretation of negative pressures experimentally obtained in the cerebrospinal fluid, I undertook with Hughson<sup>16</sup> a more extensive study, working toward narrowing the limits of accuracy of the thesis. In the literature, suggestions as to the importance of the cranial vault to the general concept had been ventured—first, by Kellie,<sup>4</sup> who noticed that in a trephined animal (*dura* opened [?]) marked variation in intracranial content of blood occurred on changes in posture. Similarly, Ecker<sup>17</sup> recorded in a trephined animal a marked diminution in the size of the brain when the carotid arteries were divided. These

observations, contrasting so strongly with the observations on animals with intact craniums, suggested the important function of the bony cranial vault as a factor in the maintenance of the closed box character of the coverings of the central nervous system.

Two types of experiments were devised by Hughson and me.<sup>18</sup> In the first series, the temporal bone on one side was trephined and the cranial vault then removed from that side, leaving the dura mater intact. With this experimental set-up it was possible to record the pressure of the cerebrospinal fluid in the customary manner and to administer intravenous injections of strongly hypertonic solutions. Freely exposed to the atmosphere, the uncovered portion of the cranial dura mater remained invariably tense, owing to the pressure of the intracranial contents against it. But freed from the cranial vault over the one side, the exposed dura could collapse inward on evacuation of the intracranial contents. Under these conditions, repeated injections of strongly hypertonic solutions, even in the amount sufficient finally to kill the experimental animal, failed to reduce the pressure of the cerebrospinal fluid to negative readings. In every case, the pressure remained slightly above zero; the positive reading (usually from 16 to 20 mm. of fluid) was apparently a direct measurement of the height of the one cerebral hemisphere above the recording needle in the mid-line of the animal. This type of experiment demonstrated, in Hughson's and my opinion, that the intactness of the cranial vault was essential for the production of negative pressures in the cerebrospinal fluid.

The experiments of the second series were of a somewhat similar nature, with provision made for the initial recording of the negative pressures in the cerebrospinal fluid and the subsequent exposure of the dura mater to atmospheric pressure. The experimental procedure involved first the trephining of the cranial vault under one temporal muscle, freeing the dura widely over one cerebral hemisphere, and subsequent sealing of the cranial opening with hard petrolatum and a glass slide. Under these experimental conditions, measurement of the normal pressure of the cerebrospinal fluid could be easily effected; after a control period, the animal was given intravenously a large dose of a strongly hypertonic solution. This injection invariably reduced the pressure of the cerebrospinal fluid to values of a negative nature. When these negative pressures were obtained, the glass slide was abruptly removed, thereby exposing the cranial dura on one side to atmospheric pressure. This exposure of the dura mater, which could under these conditions collapse inward, resulted in the prompt change of the pressure of the cerebrospinal fluid from its negative value to a positive level,

---

18. Weed and Hughson (footnote 16, second reference).

representing again the height of one cerebral hemisphere above the recording needle. These two series of experiments (Weed and Hughson<sup>19</sup>) seemed to demonstrate conclusively the essential accuracy of the interpretation of the Monro-Kellie doctrine as given by McKibben and me.

The data indicated that within the physiologic limits tested the doctrine was fundamentally correct, and that the other elements of possible disturbance to such interpretation were not of sufficient consequence to interfere with the general soundness of the doctrine. Thus, a hypothetic dilatation of the wide venous bed in the spinal epidural space, the possible stretching of the fibrous bands between the spinal dura and vertebral canal, the elasticity of the occipito-atlantoid ligament and the theoretically possible movement of fluid inward along potential perineural channels—all of which factors might be assumed anatomically and physiologically to prevent strict interpretation of the rigid character of the coverings of the central nervous system—were not of sufficient physical importance to vitiate the bony framework of the central nervous system as a closed container. All these potentially active factors seemed to be of theoretical rather than any practical significance under the conditions of observation. The experiments done with McKibben and those with Hughson did not give, however, any information regarding these potentialities; the experiments excluded these potentialities from any active rôle in the extreme conditions of the physiologic procedure, and argued strongly for acceptance of the Monro-Kellie doctrine as an essentially sound hypothesis.

It seemed, however, that these series of experiments were largely of a gross nature, and that the means employed were such as to bring out certain maximum variations rather than the minute effects which might theoretically play a rôle in the normal physical use of the bony containers of the nervous system. Slight variations in the intradural vascular bed or in the epidural tissues would not, under these conditions, be great enough to interfere with the drastic reduction of the pressure of the cerebrospinal fluid, achieved by the intravenous injection of strongly hypertonic solutions. There could, however, not be any doubt that in the wider sense the Monro-Kellie doctrine was correct. The gross limitations, through which the doctrine would hold correct, were established; but the finer, more minute limitations were not in any way determined.

For several years after the publication of the results of these investigations with Hughson, I considered methods of narrowing the physiologic limits within which the Monro-Kellie doctrine could be demonstrated to be essentially sound. Many of the suggestions which

---

19. Weed and Hughson (footnote 18, charts 1 and 2).

came to me were such as to give but little encouragement, but within the last two years I have obtained significant data from study of the changes in pressure of the cerebrospinal fluid, effected by alterations in the posture of the experimental animal. Some of the data were presented before the Association for Research in Nervous and Mental Disease (December, 1927); others are now reported for the first time.

For the experimental study of postural changes in the pressure of the cerebrospinal fluid, a simple tilting table was devised, whereby the animal, securely fastened to the table, could be abruptly changed from the horizontal to the vertical positions (head-down, tail-down). It was necessary to record not only the pressure of the cerebrospinal fluid during such changes in the animals' positions, but also the intracranial venous pressure from the sagittal sinus (Weed and Hughson), as well as the intracranial arterial pressure. For all these records, simple apparatus was used, so that the experimental procedure could be carried out by a small experimental team.

With this set-up, many interesting observations in regard to the physiology of the cerebrospinal fluid were obtained, but for the restricted purpose of this discussion, only the pertinent data will be given. First of all, it became apparent that the clinical observations of an increase in intracranial tension when lumbar pressure was measured in the erect rather than in the prone position held also for four-footed mammals. In the experimental series, with the normal pressure of the cerebrospinal fluid hovering around an average of 125 mm. of fluid, abrupt tilting of the animal to the vertical, head-down position occasioned an increase in the occipital pressure of from 90 to 120 mm. (charts 1, 2 and 3). In forty-four different observations, the average increase was 104.9 mm. of fluid in this shift from the horizontal to the vertical position, the extremes being 64 and 167 mm. On the other hand, if the animal was tilted from the horizontal to the vertical, tail-down position, a decrease of from 60 to 85 mm. occurred in the pressure of the occipital cerebrospinal fluid (chart 2), the average decrease in twenty-four observations being 74.3 mm. The extreme variations were 115 and 48 mm.

On restoration of the animals to the horizontal position, the pressures of the cerebrospinal fluid returned ultimately to the same levels as in the control periods, but not until temporary depressions had occurred after the vertical, head-down position and temporary elevations after the vertical, tail-down position (charts 1, 2 and 3). These increases and decreases from the normal level after such vertical tiltings consisted of from 10 to 15 mm. of fluid. They persisted usually from five to seven minutes, with gradual recession, normal levels being customarily restored within ten minutes. These slight differences from the normal levels of pressure of the cerebrospinal fluid are of sig-

nificance in indicating the place of absorption of the major portion of the cerebrospinal fluid and the relation of pressure to the process. With the vertical, head-down position, the pressure of the intracranial cerebrospinal fluid is increased; when the animal is restored to the horizontal position, the pressure of the cerebrospinal fluid is below that which existed before the tilt to the vertical position. The exact converse holds when the tilting is in the opposite direction. These observations would seem to indicate that the major absorption of the cerebrospinal fluid is unquestionably in the head region, and that with

Chart 1 (dog—experiment A 18).—In this and the following charts, the ordinates represent millimeters of Ringer's solution or mercury (carotid pressure); abscissae, time in minutes; solid black line, cerebrospinal fluid pressure from occipito-atlantoid manometer; interrupted line, sagittal venous pressure; rings and dashes, brachial venous pressure; solid circles and dashes, carotid arterial pressure. The animal was in a horizontal position except during the interval marked by the solid block, in which it was shifted to a vertical, head-down position.

increased pressure in the cranial cerebrospinal fluid an increased absorption takes place.

Other changes of significance occurred during this tilting process, particularly in the cerebral venous pressures, as measured in the superior sagittal sinus (charts 1 and 2). The average increase in sagittal pressure in the same series of observations, with tilting of the

## WEED—MONRO—KELLIE HYPOTHESIS

animal from the horizontal to the vertical, head-down position, was 184.1 mm., as compared with an increase of 104.9 mm. in the pressure of the occipital cerebrospinal fluid. In the converse experiments, on tilting from the horizontal to the vertical, tail-down position, the average decrease in sagittal pressure was 79.7 mm., as compared to the average decrease of 74.3 mm. in the pressure of the occipital cerebrospinal fluid. The alterations in the systemic venous pressure (chart 3) were not of significance during this process of abrupt tilting from the horizontal to the vertical; similarly, the alterations in the intracranial arterial pres-

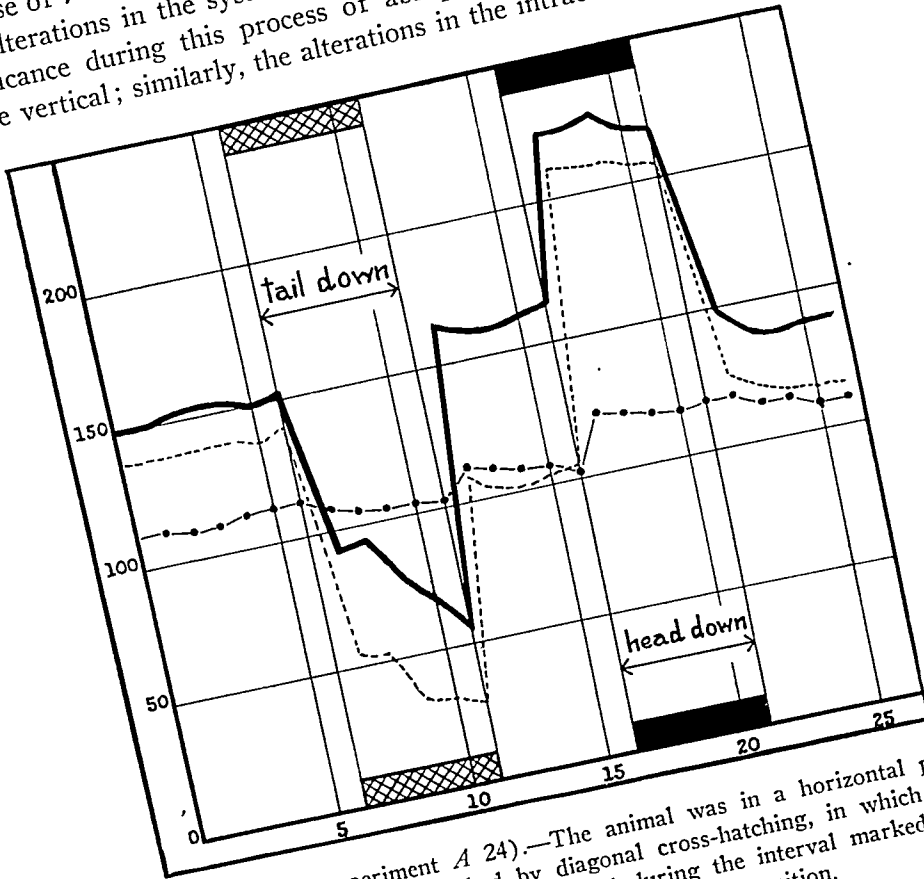

Chart 2 (dog—experiment A 24).—The animal was in a horizontal position except during the interval marked by diagonal cross-hatching, in which it was shifted to a vertical, tail-down position, and during the interval marked by the solid block, when it was shifted to a vertical, head-down position.

sure (charts 1, 2 and 3) were likewise not of real importance in the discussion. The general observations indicate, therefore, that the pressure of the cerebrospinal fluid is less affected by postural changes than is the pressure of the cerebral venous system.

In some animals, the pressure of the cerebrospinal fluid was taken simultaneously by occipito-atlantoid and lumbar manometers. Under these conditions, during the control periods when the animal was in the horizontal position, the occipital and lumbar pressures were at the same

levels. When, however, the animal was tilted from the horizontal to the vertical, head-down position, the increase in the occipital pressure was far greater than when the dural tube was pierced by only one needle (chart 3); negative pressures occurred in the lumbar manometer. In one animal, the occipital pressure increased from 120 to 240 mm., while the lumbar pressure fell to minus 100 mm. With the animal in the vertical position, the occipital and lumbar manometers were in the same vertical plane, side by side. The fluid in the two manometers could be seen under these conditions to be at exactly the same level, though in the experimental set-up the lumbar manometer recorded a

Chart 3 (dog—experiment A 8).—The animal was in a horizontal position except during the intervals marked by the solid blocks, in which it was shifted to a vertical, head-down position. During the interval, from 57 to 68 minutes, lumbar puncture was done.

negative pressure, while the occipital instrument recorded a positive pressure. When the animal was restored to the horizontal position, both these manometers showed resumption of normal pressures.

One of the phenomena noted in all these experiments was the relatively rapid fatigability of the vasomotor system on such abrupt tiltings to the vertical. In many animals, spontaneous respiration ceased and vasomotor collapse seemed to occur. Others of the animals seemed to stand these abrupt changes in posture well, and fatigue in reaction was not apparent, even after many tiltings. In one animal (chart 4),

five abrupt tiltings at five minute intervals were carried out in seventy-seven minutes of experimentation; fatigue was practically absent throughout the period. The magnitude of the postural alterations is, however, of some significance in the general process, as in this animal the decreases in the pressure of the cerebrospinal fluid were as follows: 40, 70, 60, 48 and 74 mm. The decreases in sagittal venous pressure for the same tiltings were 65, 69, 59, 45 and 47 mm. Such variations are, of course, not unexpected in any physiologic reaction, but the curve indicates a gradual decrease in the pressure of the cerebrospinal fluid, together with a gradual increase in the sagittal venous pressure.

#### COMMENT

All these data have immediate significance in the limitation of the field of accuracy of the Monro-Kellie doctrine. In this series of laboratory mammals (cats and dogs), the average distance between the occipital recording needle and the last lumbar spine was slightly over 400 mm. The average alterations in the pressure of the cerebrospinal fluid on tilting from the horizontal to the vertical positions were 104.9 mm. for the head-down position, and 74.3 mm. for the tail-down position. These alterations in the pressure indicate, therefore, that in the vertical position the full hydrostatic effect of the column of 400 mm. of water is not superimposed on the existing normal pressures. For, if this column were superimposed in its entirety, the pressure of the occipital cerebrospinal fluid should increase approximately 400 mm. when the animal is tilted from the horizontal to the vertical, head-down position; and, conversely, the decrease should be of the same extent, giving negative pressures in the cerebrospinal fluid, when the animal is tilted to the vertical, tail-down position.

Similarly, the magnitude of the alterations in the pressure of the cerebrospinal fluid in these experimental procedures indicates that the spinal dural tube does not serve as an absolutely rigid container, for if the tube were a truly rigid container, the tiltings from the horizontal to the vertical positions, either tail-down or head-down, should not in any way affect the pressure of the occipital cerebrospinal fluid, the tube being to all intents completely filled with fluid. The tilting experiments with manometers in both occipital and lumbar regions are important here: the second needle serves to vent the tube and permits dislocation of the spinal fluid as indicated by the greater increase of pressure in the dependent needle when compared with the lesser increase in animals without a lumbar opening (chart 3). The fact that alterations in the pressure of the cerebrospinal fluid do occur in abrupt tilting from the horizontal to the vertical, even when the tube is not vented, indicates that the physics of the hydrostatic column of water cannot be directly applied: the extent of the alterations in pressure, however, demonstrates

that in many ways the spinal dural tube does act as a partially rigid container. Venting of this tube which thus allows atmospheric pressure to affect the fluid column through one of the recording manometers, as in those animals in which simultaneous records of occipital and lumbar pressures were obtained, shows that a partial vacuum must, under ordinary conditions, be created within the uppermost portion of the tube, when the animal is in the vertical position.

These observations lead, therefore, to speculation regarding the anatomic and physiologic mechanisms which permit, under these conditions, the partial application of the hydrostatic column to the pressure of the cerebrospinal fluid when the animals are in the vertical positions. Two factors of extreme importance seem immediately indicated: (1) the possible inward collapse of the spinal dura mater, and (2) the alteration in the intradural venous bed (dilatation or constriction). Reducing the problem to its simplest form, in the case of the animal tilted from the horizontal to the vertical, head-down position, with resultant increase in the pressure of the occipital cerebrospinal fluid of approximately 100 mm., it becomes apparent that this increase in the pressure must have been due to dislocation of the spinal column of fluid, permitted by partial collapse of the spinal dura or by dilatation of the intradural veins in the spinal region. The first of these two factors might be due to stretching of the small fibrous trabeculae, extending across the epidural space from the inner surface of the rigid vertebral column to the outer surface of the dura mater. Such a hypothetical stretching of fibrous trabeculae might also be accompanied by dilatation of the veins in the extensive epidural plexus. This stretching would probably occur to the greatest extent in the lumbar and sacral regions of the cord, for in these regions the negative pull of the column of water would, in the vertical position, be most extreme.

The second factor which might play an important rôle in such an increase in occipital pressure, with the animal in the vertical position, is the dilatation of the intradural veins in the lower spinal region. Such a hypothetical dilatation would affect the thin-walled veins transverse the subarachnoid space, the extensive venous bed directly beneath the pia mater and possibly the venous bed of the spinal cord itself. This assumed dilatation of veins would decrease the space occupied by the column of cerebrospinal fluid under normal conditions, and would, therefore, permit dislocation of the fluid from the lumbar and sacral regions when the animal is in the vertical, head-down position. This dislocation would be equivalent to a decrease in the height of the fluid column; it would have the same physiologic effect as inward collapse of the dura mater.

Some information regarding the relative importance of these two possible factors in allowing a partial hydrostatic effect to be manifested

in tilting from the horizontal to the vertical positions can be obtained. The basis for this statement lies in the differences recorded in the pressure of the cerebrospinal fluid when the animals were tilted from the horizontal to the vertical, head-down and tail-down positions. In the former case (tilting from horizontal to vertical, head-down position), the average increase in occipital pressure was 104.9 mm. of fluid; while in the latter case (tilting from horizontal to vertical, tail-down position), the average decrease was 74.3 mm. In both these tiltings, the recording needle was in the same place (i. e., through the occipito-atlantoid ligament in the midline), and the same column of fluid was imposed on the normal pressure, though in different directions. Were the dilatation of intradural veins in the uppermost part of the animal the important factor, the decrease when the animal is tilted from the horizontal to the vertical, tail-down position should be greater than when it is tilted from the horizontal to the vertical, head-down position. In the former tilting, the dilatation of the relatively enormous cerebral veins, allowing outspoken dislocation of the fluid column, would be theoretically possible. However, with the recorded increase in pressure of the occipital cerebrospinal fluid on tilting from the horizontal to the head-down position exceeding the decrease on tilting from the horizontal to the vertical, tail-down position, it must be assumed that the inward collapse of the dura mater is the more important factor in such superimposition of hydrostatic effect on the normal pressure of the cerebrospinal fluid.

The inward collapse of the dura mater, which seems essentially responsible for the postural dislocation of cerebrospinal fluid, occurs, in all probability, to a greater extent in the lumbar and sacral regions than in the thoracic and cervical areas. The evidence for this again depends on the greater alteration in pressure of the cerebrospinal fluid on vertical tilting to the head-down position than on tilting to the tail-down position. In the former case, it seems logical to assume a collapse of the dura mater against the spinal cord in the region where the spinal cord is rapidly diminishing in size, whereas, in the latter case, the cervical enlargement apparently tends to prevent great inward collapse of the dura mater. The relative sizes of lumbar and cervical portions of the subarachnoid space would here appear to be responsible.

It seems rational also, on the basis of this argument, to assume that a theoretically possible compression of veins in the dependent portion of the nervous system on vertical tilting plays practically no rôle in the process of dislocation of the fluid. Were such a compression of veins a factor of significance, the recorded changes in cerebral venous pressure would not exceed the changes in the cerebrospinal fluid pressure, for the pressure of the fluid on the outside of the veins would necessarily have to equal or exceed that within the veins to secure such mechanical compression. Also, if the veins in the dependent part of the nervous

system were compressed by the surrounding cerebrospinal fluid on such vertical tilting, dislocation of spinal fluid would not occur, unless at the upper end of the vertical system such a dislocation of fluid were at the same time permitted by other factors.

On the other hand, the major emphasis given in the foregoing paragraphs to the importance of inward collapse of the spinal dura mater does not seem to tell the whole story. The extent of the alterations in the pressure obtained on each successive tilting in one animal should be almost exactly the same, were the inward collapse of the dura mater the entire factor in the process of dislocation of the spinal fluid. This inward collapse of dura mater, permitted by stretching of the epidural trabeculae, must be looked on largely as an anatomic phenomenon, and

Chart 4 (dog—experiment A 33).—The animal was in a horizontal position except during the intervals marked by the solid blocks, in which it was shifted to a vertical, head-down position.

the process should, therefore, not be subject to greater variation within the period of experimentation. In the animal the reactions of which are set down in chart 4, the variations in the alterations of pressure of the cerebrospinal fluid were considerable; and these variations, occurring within five or ten minutes in the same animal, with coincident changes in the pressures in the superior sagittal sinus, would indicate that the factor of vasomotor readjustment still had some importance. In consequence, it is not in any way possible to exclude from this explanation the theoretical dilatation of the intradural veins in the uppermost portions of the spinal cord when the animal is in the vertical positions; this dilatation must play a rôle of unknown importance in permitting downward dislocation of spinal fluid.

## CONCLUSIONS

These phenomena of alterations in pressure in the cerebrospinal fluid on change in the animal's posture lead to the general conclusion that the mammalian central nervous system is protected in large measure against changes in pressure due to postural adjustments, as the full effects of the hydrostatic column of fluid, theoretically possible, are not superimposed in the vertical position on the normal pressure of the cerebrospinal fluid. The extent of these variations in pressures, on abrupt tilting to the vertical positions, are in accord with the clinical observations by Barré and Schrapf,<sup>20</sup> and by Zylberlast-Zand;<sup>21</sup> in these, an increase of approximately 200 mm. in pressure of the lumbar cerebrospinal fluid was recorded in man on change from the prone to the vertical position. Were the central nervous system not held within a relatively rigid container, the full extent of the hydrostatic column of fluid should be recorded both in the four-footed animal and in man. In the laboratory mammals used in these experiments, this column of fluid measured approximately 400 mm., while in man the analogous distance between occiput and last lumbar spine is between 575 and 600 mm. Roughly, from one third to one fourth of this actual column of fluid makes its effect felt on postural adjustment; in other words, the spinal tube of mammals is fairly, though not absolutely, rigid. Within these physiologic limits, as tested in the experiments on mammals, the spinal tube does not serve as an absolutely rigid container, yet the effect of the rigidity of the tube is such that only a fraction of the hydrostatic height of the contained column of fluid makes itself felt.

This assumption of relative rigidity in the spinal dural tube delimits again the general accuracy of the Monro-Kellie hypothesis, for in this doctrine it is necessary to include the spinal tube as well as the cranial portion. On the basis of these experiments, the Monro-Kellie thesis may still be assumed to be essentially correct; but the correctness of the doctrine does not seem to be as absolute, as in the experiments recording negative pressures of the cerebrospinal fluid. In these former observations, the theoretical or actual collapse of the spinal dura against the spinal cord, and the theoretical or actual dilatation of the spinal veins, play rôles of relatively small significance, as shown by the extreme negative pressures so frequently obtained.

There are, of course, other limitations to the Monro-Kellie thesis. In the recorded literature on the subject, but little mention has been made of the fact that all the discussions of the doctrine are based on

the anatomic arrangements in the adult; consideration is not given to the anatomic disposition in the new-born babe and in other new-born mammals, where fibrous sutures and fontanels characterize the skull at the time of birth. The pulsations of the anterior fontanel in the new-born babe have been noted for almost 2,000 years, and the elasticity of these fontanels would, of course, vitiate extreme interpretation of the accuracy of the *Monro-Kellie thesis*. As pointed out in other paragraphs, however, the elasticity of the occipito-atlantoid ligament in the adult would similarly affect the absolutely rigid character of the containers of the central nervous system; and in the new-born child the insertion of such an elastic membrane in a large portion of the cranial vault would unquestionably tend to have a far greater effect on the *Monro-Kellie hypothesis* than would the persistence of a small elastic window in the occipital region.

It was, of course, extremely important to have Blackfan, Crothers and Ganz <sup>22</sup> argue so clearly that in children the *Monro-Kellie hypothesis* should not be applied with exactness; but it should not be assumed that it is possible to discard the thesis entirely in the new-born child and in young infants. Nanagas' <sup>23</sup> experiments on hydrocephalic kittens are pertinent to the discussion. In the series of young kittens in the first few weeks of life, Nanagas created an experimental hydrocephalus by injecting suspensions of lamp black into the cerebral ventricles or sub-arachnoid space (Weed <sup>24</sup>). Following this procedure, the skulls of these kittens increased enormously in size, the suture lines enlarged and the fontanels became wide, elastic membranes. The intraventricular pressure of these hydrocephalic kittens was approximately 50 per cent higher than the pressures in the control litter mates. When given intravenous injections of strongly hypertonic solutions, the intraventricular pressure of the hydrocephalic kittens in Nanagas' series was frequently reduced to negative values. The skull of these kittens, with such negative pressures existing within the nervous system apparently collapsed in part, the flat cranial bones coming to over-ride each other so that a fairly rigid skull was reestablished. The obtaining of such negative pressures in the experimental kittens would indicate that in the new-born mammal the *Monro-Kellie doctrine* should be looked on as a fairly potent factor in intracranial physiology. The limitations here, however, are much greater, owing to the extreme elasticity of the

anterior fontanel and the wide extent of this elastic window, than in the case of adult animals, in which the whole cranial vault is bony. That the intactness of a major portion of the cranial vault is necessary for the essential working of the closed box character of the containers of the central nervous system was shown by the experiments done with Hughson. The question is one merely of the limitations of the *Monro-Kellie* thesis rather than of its incorrectness.

In the *Monro-Kellie* doctrine, then, there exists a hypothesis which within tested physiologic limits must be considered essentially sound, though in minor ways the doctrine does not hold. The evidence points to the cranial cavity as an intact closed container; in the spinal dura mater, there exists a fibrous membrane which is not held outwardly with great rigidity. The spinal region, therefore, constitutes the part of the central nervous system which is apparently not confined within an absolutely rigid container; but the importance of this part of the central nervous system is relatively not as great as the cranial portion. So in almost every physiologic way, the *Monro-Kellie* doctrine must be considered essentially correct, though such consideration must be always subject to special limitation. From the standpoint of intracranial physiology, as a basis for experimental or surgical procedures, the doctrine holds; and its importance is great in any clinical procedure.

It is thoroughly stimulating to contemplate again the gradual development and delimitation of this important doctrine of intracranial anatomy and physiology, for in this doctrine there have been elements of romance and speculation. Taking its inception as an explanation of intracranial physiology logical to its time, *Monro*<sup>1</sup> limited the doctrine strictly to the cranium, and being ignorant of the existence of the cerebrospinal fluid and of the variability of brain volume, he developed the hypothesis in relation only to the intracranial blood volume. Then, in *Kellie's* fascinating studies, there seemed to exist pathologic and experimental proof of the hypothesis. Again, with the increasing dissemination of knowledge regarding the cerebrospinal fluid, *Burrows* was able to add another element to the consideration, and to accept the doctrine as a generality, though limiting it in a rather specific way.

The introduction of modern experimental methods, especially the attempted study of the cerebral blood volume by direct observation through a cranial window, added but little in the initial researches, owing to the difficulty of examining more than a local area of the central nervous system and to the necessity of limiting the observations to the relatively large cerebral arteries and veins. But this method, in the final analysis, must give the information needed; and it is of great significance that renewed efforts to this end are now being

carried forward. The recent studies by Forbes and Wolff<sup>25</sup> are technically a great improvement over the earlier investigations by an analogous method of direct observation; with Kubie's introduction of colored photography into the procedure, data regarding the cerebral capillary volume will soon be available as well as information regarding the calibers of the superficial cerebral arteries and veins. All these methods, to be of final service, must, however, be subject to some type of calibration or standardization, in order that these observations may be carefully checked against the physiologic measurements of intracranial pressures.

With such methods at hand, knowledge regarding the mechanism of compensation between the three elements filling the cranial cavity may be had, so that the problem will be taken from the field of speculation to that of definite physiologic demonstration. However, at present, it seems thoroughly logical to conclude that in a major way the Monro-Kellie thesis will, in the future, be held to be essentially correct. The gradual accumulation of the known limitations of the doctrine will serve to strengthen the reliance on the major discussion rather than to weaken it.

# INSTRUMENTAL DILATATION OF THE PAPILLA OF VATER AND THE DISLODGMET OF CALCULI BY RETROGRADE IRRIGATION

A CONTRIBUTION TO THE SURGERY OF THE BILE PASSAGES\*

DAVID CHEEVER

The problem of the safe and certain removal of calculi from the common bile duct and of the restoration of its permeability is often a pressing one in the course of operation for cholelithiasis. Its solution must be by simple mechanical methods which should occur to any resourceful surgeon even though the exact problem has never presented itself before. The frequency, however, with which patients apply for the relief of symptoms due to calculi in the common duct overlooked at a previous operation leads to the conclusion that the methods in general use by surgeons are not efficient. This impression is strengthened by observations recently in twelve European clinics, in not one of which were satisfactory measures to explore the common duct apparently in routine use, and by a nearly similar experience in this country.

Calculi in the common duct offer three avenues of approach, according to the part of the duct which they occupy. In the supra-duodenal portion where the duct lies between the layers of the gastro-hepatic omentum, incision may be made directly into the duct; in the retroduodenal part of its course it may be reached by mobilizing the second portion of the duodenum and traversing, if necessary, the edge of the pancreas; and, finally, if the stone is lodged in the ampulla of Vater or is impacted in the opening of the papilla, it may have to be reached by opening the bowel and slitting open the papilla itself. The first of these methods is much to be preferred, since it involves the fewest technical difficulties and the fewest opportunities for secondary complications. Fortunately, most calculi can be removed by that route, with the aid of manipulation to press them up into the operative field or of scoops which engage them.

Every surgeon is keenly aware of the impossibility of being absolutely sure that calculi have not escaped any method of detection, or that small fragments and detritus do not remain in the duct to form the core of future concretions. It is notorious that the retroduodenal portion of the duct is extremely difficult to palpate with accuracy, both on account of its position, and because the somewhat lumpy, uneven consistency of the pancreas, in whose substance the duct is enfolded,

---

\* From the General Surgical Service, Peter Bent Brigham Hospital, Boston.

makes the identification of a small concretion uncertain. This difficulty is enhanced, of course, in the numerous instances in which a degree of chronic pancreatitis is present. As a calculus of any size must almost inevitably block the passage of an instrument through the duct and its papilla into the duodenum, the failure of such an instrument to pass must be construed as probably being due to the presence of a concretion, unless it can be shown to be caused by stricture or by the catching of its tip in a fold or diverticulum.

The first step, then, in proving that all stones have been removed from the duct should be the demonstration of its patency by the passage of a suitable instrument from an incision in the supraduodenal portion of the duct downward through the papilla into the duodenum. This has usually been attempted with a rigid metal probe or sound. Too often the surgeon is satisfied to pass this down for a distance corresponding to the estimated length of the duct and to assume that its tip must have entered the bowel. Normal variations in the length of the duct, the elasticity of the tissues which enables the tip of the sound to become engaged in the ampulla and to push its wall along for some distance, the possibility of the instrument making a false passage in the duodenal wall or periduodenal tissues, all combine to make such an assumption fallacious. It cannot be insisted too strongly that the only certain criterion of the successful passage of an exploring instrument through the duct into the bowel is the use of a hollow instrument and the injection of fluid which passes freely into the viscus and does not flow back around the instrument and appear at the incision in the bile duct.

#### DILATATION OF THE PAPILLA

Since, as noted, the most meticulous care sometimes fails to clear the duct of all debris, especially if one or more larger calculi have been somewhat fragmented by exploring scoops, the surgeon at once thinks of the expediency of dilating the opening of the papilla in order that the fragments may subsequently be washed down into the duodenum, either at the time of operation by the irrigating fluid or later by the current of bile itself. Such a procedure at once involves a consideration of the function of the sphincter and of the question as to whether or not such dilatation may do harm as well as good.

It is clear that nature did not intend that the contents of the duodenum should enter the bile passages lest harm might result in at least two ways: (1) from infection and (2) from chemical or fermentative irritation. Normally, the bacterial flora of the small intestine does not have its habitat at so high a level, but it is well known that the colon bacillus and other pyogenic organisms are sometimes recovered from the duodenum, and it is believed that a few at least of the

instances of cholangitis are caused by infection from this source, although the majority doubtless may be due to infection from the blood or lymph stream through the mediation of the gallbladder. The ferments of the pancreatic juice are relatively harmless as they flow into the ampulla of Vater, but after passing through the papilla they are at once activated by the duodenal contents and secretions and become intensely proteolytic and capable of digesting and destroying tissues, so that if they reenter the duct, or if they become activated by the entrance of duodenal contents into the ampulla, they may have a harmful action on tissues unprovided with natural defenses against them, causing a serious complication, instances of which will be given later. Moreover, the physical structure of the papilla itself is apparently designed to prevent regurgitation into the duct. Its lumen is extremely narrow and passes through a small conical elevation in the wall of the bowel, composed in part of smooth muscle fibers the sphincteric action of which was first described by Oddi, and which apparently effectively close the orifice except when the muscle tonus is inhibited or overcome to permit of the passage of bile and pancreatic juice.

Since Courvoisier<sup>1</sup> performed the first choledochotomy in 1889, and McBurney,<sup>2</sup> the first transduodenal operation on the duct in 1894, surgeons have gradually brought to greater perfection the methods of exploration of the bile passages. The use of simple probes to demonstrate the calculus by impinging on it or to guide the externally palpating finger was succeeded by the employment of scoops and of irrigating instruments to facilitate its removal. There followed naturally the demonstration of patency of the papilla by the passage of sounds into the duodenum. Just when the purposeful dilatation of the papilla to permit evacuation of debris into the duodenum began is not clear. Robson,<sup>3</sup> in 1906, advised the passage of a probe into the bowel to demonstrate the absence of calculi. McArthur<sup>4</sup> described the introduction of a rubber drainage tube downward into the duct and the passage of a small urethral catheter through the papilla, thereby supplying fluid and nourishment directly to the bowel. Matas<sup>5</sup> described essentially the same procedure and mentioned the dilating

of the passage with graduated catheters up to no. 30 F. Hofmeister<sup>6</sup> spoke of the impossibility of certainty on the part of the surgeon that some detritus did not remain in the duct and told of his adoption of methodical dilatation with urethral bougies as large as nos. 22 or 24 or even 30 F., followed by the introduction downward of a rubber drainage tube which projected from 3 to 4 cm. into the duodenum, and fulfilled three objects: the maintaining of the dilatation of the papilla, the provision of a prophylactic enterostomy to empty the intestine and a means of the injecting of nutrition mixed with bile obtained from another common duct tube introduced upward. Pototschnig<sup>7</sup> discussed ideal choledochotomy and cited seven cases of removal of stones through a supraduodenal incision in the duct followed by progressive dilatation of the papilla to no. 24 F. with a Hegar urethral dilator followed by primary suture of the duct. Rost,<sup>8</sup> Haberer,<sup>9</sup> and Enderlen<sup>10</sup> discussed the advantage of progressive dilatation of the papilla, establishing what they call "internal drainage" of the duct with a view to permitting primary suture of the incision into the duct and closure of the abdomen without drainage.

With the German school, this dilatation for the establishment of "internal drainage" appears to be quite as much to avoid the occurrence of increased pressure of bile within the duct and consequent leakage of the sutured wound as it is to promote the escape of small calculi and detritus into the bowel. Some radical measures have been proposed and carried out with this object in view. Thus, Walzel<sup>11</sup> discussed three procedures after supraduodenal choledochotomy to secure this result: first, transduodenal choledochotomy, laying open the papilla by incision and suturing the flaps to the duodenal wall; second, anastomosis of the divided dilated duct to the bowel, thus sidetracking the papilla, and, third, instrumental dilatation of the papilla through the supraduodenal wound. He concluded that the first two methods are too radical, and that the last is safe and effective. He cited twenty-five cases from von Eiselsberg's clinic in which he carried out instrumental dilatation with graduated sounds and a small Kollman's urethral

dilator armed with a knife with which he was accustomed to dilate the papilla to no. 24 F. In one instance, when death from gastric hemorrhage had occurred five days after operation, it was found at autopsy that the opening still remained open. To this procedure he sometimes added intubation with a rubber tube projecting into the bowel. Lorenz,<sup>12</sup> after stating the impossibility of certainty on the part of the surgeon as to whether any method has adequately cleared the duct, and quoting the statement of Kehr that even with the best technic stones are overlooked in from 10 to 15 per cent of cases, advised as a routine the opening of the duodenum and the establishment of drainage by slitting the papilla or making a separate opening through the mucous membrane into the duct above the papilla and suturing the edges of the flaps to the bowel wall to maintain patency. He mentioned as an additional advantage of the method the possibility of inspection of the opening of the duct of Wirsung, although he admitted that he never found a calculus there. He quoted sixty-three cases in which this method was used, with twelve deaths, a mortality of 19 per cent. It would seem that such a mortality is far more serious than the morbidity and possible ultimate mortality resulting from gallstones overlooked by less radical measures. Körte<sup>13</sup> reviewed the progressive dilatation as practiced by Hofmeister and the more radical procedures of Lorenz, which he regarded as extreme and likely to lead to infection of the bile passages. Mayo,<sup>14</sup> in contrast to the aforementioned more drastic procedures, advised that an opening should be made by gentle instrumentation through the papilla into the duodenum, sufficient to permit undetected stones to pass later. He stated that in nearly one third of the patients who died following operations on the common duct for stone, postmortem examination showed that all stones had not been removed. Desjardins<sup>15</sup> described exploring instruments of known caliber, exactly like those for the urethra, flexible in order to follow the curves of the duct, and metallic in order to give a sound on meeting a calculus. He did not speak of actually passing his instruments into the duodenum or of dilating the papilla. Deaver<sup>16</sup> spoke of graduated dilatation of the sphincter of the papilla in case it is

strictured and said that most cases of "recurrent" stones after cholecystectomy and choledochotomy have been in reality overlooked. He believed that after cholecystectomy there is probably a marked increase of intraductal pressure which persists for a week or longer until the sphincter of Oddi becomes incompetent. He inquired whether this might not account in some instances for postoperative vomiting. Many other authors mention less specifically various methods of instrumentation of the bile ducts.

#### METHOD OF DILATATION

Since the opening of the Peter Bent Brigham Hospital in 1913 (and less systematically at other clinics before that date), I have practiced bouginage and gradual dilatation of the lumen of the papilla of Vater, whenever possible, in every patient in whom the common duct was opened and explored. Observations had been made for some years on cadavers in the dissecting room of the Harvard Medical School which showed that the normal lumen of the papilla corresponded to no. 10 of the French scale, and that gradual and gentle dilatation could be carried out to no. 18 or no. 20 F. without laceration of the papilla. It was recognized that accurate comparison could not be made in this respect between dead and living tissues, but these observations formed a proper basis for developing a plan of procedure. The method at operation is as follows:

The duct is exposed and the epiploic foramen freed of obstructing adhesions, if present, to permit palpation of the duct between the thumb and forefinger. Frequently, the duodenum is slightly mobilized to allow the retroduodenal portion to be examined in the same way, and to determine the condition of the head of the pancreas. The supraduodenal part of the duct is incised, and any calculi which are present are expelled by gentle manipulation. The duct is completely cleared so far as possible by the repeated passage of a small scoop first downward and then upward. A no. 10 F. woven silk elastic, olive-tipped urethral catheter, rendered flexible and soft by immersion in a warm bath is passed downward until its tip is felt to slip through the narrowed lumen of the papilla, and the fact of this complete passage is invariably confirmed by the injection of a sterile solution of sodium chloride which fails to flow back around the catheter if its fenestration has passed beyond the papilla. Occasionally several hundred cubic centimeters of fluid have been injected to combat dehydration, but this has not been considered important, and the tendency of the fluid to flow back after dilatation has been completed may be embarrassing. The no. 10 instrument is followed in turn by nos. 12, 14 and 16 and, in certain cases, by nos. 18 and 20. If the lumen is found to have been dilated already by calculi to this extent, no further stretching is attempted. If the tip of the first catheter is obstructed apparently by a fold of mucous membrane in the dilated ampulla, a larger sized instrument may fail to get thus entangled and may pass. In two instances success has been attained by the method used in stricture of the urethra, that of allowing a small bougie to become entangled in the pocket and passing a second instrument beside the first. With the withdrawal of each catheter the duct is vigorously flushed out. The hepatic ducts are washed out in the same manner so far as is feasible:

the scoop is passed again and a final retrograde flushing made. A soft rubber drainage tube of suitable size is then passed upward into the duct and secured in place by a no. 00 chromic gut stitch which includes the slightest possible edge of the duct wall, and the rest of the incision in the duct is closely sutured around the catheter to prevent leakage.

What danger may threaten from this routine dilatation of the papilla? Rost<sup>6</sup> recorded a fatal result: The patient had had a previous choledochotomy, and five years later a stone was removed from the much dilated common duct. The lumen of the papilla was narrow, but could be gradually dilated to no. 6 Hegar. The duct was sutured and the abdominal wound drained. Death occurred in twenty-four hours. Autopsy showed much bile in the peritoneal cavity (none had appeared externally), acute hemorrhagic pancreatitis, edema of the papilla and of the surrounding tissues. Rost believed that the dilatation of the papilla did not make it more patulous but less so on account of the edema, and that the bile backed up, and under tension leaked into the peritoneal cavity and also into the pancreatic duct, causing acute pancreatitis. If this view is correct, it is a serious indictment of the method, but to me it seems more likely that there was instrumental injury to the duct of the pancreas and that the edema of the papilla was secondary to the acute pancreatitis. The mistake in attempting the "ideal" suture of the duct in such a case is evident. This fact, was admitted by Rost, who stated that he had given up the procedure. Haberer<sup>9</sup> reported an instance in which he performed "bloodless dilatation" of the papilla with a metal sound, no. 16, which passed without resistance into the duodenum. At autopsy, death was found to have been caused by peritonitis, due to the fact that the sound had been pushed through the wall of a thin diverticulum of the common duct and also tore the wall of the duodenum. It is apparent that if soft silk-web catheters had been used and the accuracy of the result confirmed by the irrigation test, this accident would have been either avoided or detected. Lorenz,<sup>12</sup> in recording twelve deaths in sixty-three cases, did not state his views as to the exact responsibility, but it may be assumed that the three deaths from diffuse cholangitis and the single death from peritonitis were related to the operative technic employed. Enderlen<sup>10</sup> mentioned that Alapy, after severe dilatation, saw duodenal contents come out, and that it was probable that he had torn the duodenum.

In the literature quoted, there is scarcely mention of the possibility of harm from the reflux of duodenal contents through the common bile duct. Davis<sup>17</sup> made an important contribution to this topic, recording two personal experiences.

17. Davis, Lincoln: *Reflux of Duodenal Contents through the Common Bile Duct*, New England J. Med. 200:313 (Feb. 14) 1929.

## REPORT OF TWO CASES (DAVIS)

CASE 1.—In a woman, aged 39, he removed the gallbladder containing calculi and drained a dilated common duct with a soft rubber catheter; no stones were found. Enormous quantities of bile-stained fluid drained from the wound, which broke down and was extensively digested. In spite of every expedient, the patient died on the seventeenth day, no autopsy being obtained.

CASE 2.—A second patient, a man aged 40, presented symptoms of stone in the common duct. At the first operation, the gallbladder was removed; two large soft stones were removed from the duct in fragments, a probe was passed down into the duodenum, the duct was washed out and a rubber tube sutured into it. The drainage was at first apparently pure bile, but on the tenth day it assumed the character of duodenal contents and digested the tissues of the wound. The amount of drainage was prodigious. The patient's condition was precarious, but he finally recovered and was discharged. Six months later at a second operation, another calculus was removed from the duct, which was washed out and drained. Convalescence was uneventful, but two weeks after the patient had left the hospital, the wound reopened and discharged bile, and he became jaundiced. At a third operation, another soft stone was removed from the enormously dilated duct, and a no. 14 F. soft rubber catheter was passed through the papilla into the duodenum for 8 inches; the upper end was anchored in the wall of the duct. A larger catheter was passed upward and the duct sutured about it, the end being brought out of the wound. At the end of forty-eight hours, a profuse discharge began, and the wound broke down completely with signs of active digestion. The patient's condition rapidly became alarming, but under heroic treatment, including the performance of a jejunostomy, transfusion and the maintenance of a clean wound by constant suction, recovery finally ensued. The duodenal tube was passed by rectum about eight weeks afterward.

Davis quotes Codman and Walters each as describing a case in which huge quantities of fluid drained out after instruments were passed through the duct and papilla into the duodenum, but in each case there was no autodigestion, and recovery was uneventful. Codman felt that in his patient there was obstruction of the third part of the duodenum by the root of the mesentery, causing intraduodenal backpressure which made fluid pass into the patent opening of the papilla. Davis cites three instances in which roentgenologists visualized the common, and some of the hepatic, ducts by the passage of barium sulphate through the papilla from the duodenum, without ill results. His conclusion is that the patency of the papilla should be determined with the greatest care and "undue dilatation scrupulously avoided."

## COMMENT

If the escape of duodenal contents with their active digestive ferments were a common incident after exploration of the common duct, this operation would approximate the great mortality in cases of duodenal fistula. As a matter of fact, a fairly comprehensive search of the literature, as noted, revealed only four cases of such reflux, one of which was fatal. Fatalities attributable to progressive dilatation of the lumen of the papilla of Vater in the course of operations on the

bile passages appear to be few, and to be due to gross and avoidable errors in technic. In further confirmation, I quote my own experience: In the course of 300 operations on the biliary tract, I have performed bouginage, usually with progressive dilatation, approximately fifty times. In no case has reflux of duodenal contents been noted. Among these fifty cases four deaths have occurred as follows: one (C. S.) from pulmonary embolism, one (C. F. J.) from uremia, one (J. F. S.) from myocardial failure and one (M. B. R.) from acute yellow atrophy of the liver. In none of these cases was the particular operative technic in any way responsible for the fatal issue. In the whole series of 300 operations there have been six deaths.

Another advantage of the method of exploration of the common duct advocated is the ease of practicing retrograde irrigation to dislodge calculi and debris from the ampulla of Vater and float them up to the incision in the supraduodenal portion of the duct. The olive-tipped elastic catheter, usually no. 10 or no. 12 F., is passed downward through the papilla, as is demonstrated by the failure of the injected fluid to regurgitate and by the obvious filling of the duodenum. While the injection is continued, the catheter is slowly withdrawn until fluid flows out of the incision into the common duct, which indicates that the fenestration of the catheter lies just within the papilla in the most distal part of the ampulla and necessarily beyond any calculi or fragments. At this point the injection is stopped, the syringe refilled, and then a much more forcible injection made and continued while the catheter is rapidly and completely withdrawn. The resulting reflux almost inevitably will float up calculi to the incision in the duct where they may be seized or scooped out. The procedure may be repeated until the operator is satisfied. A suction nozzle placed in the deepest part of the subhepatic fossa against the walling-off gauze is useful in aspirating the irrigation fluid. The operation is finished by directing a soft rubber tube upward in the common duct and securing it by a fine catgut suture, which also closes the incision in the duct around it.

It is not intended to claim either originality or priority for these measures to relieve patients with common duct lithiasis. They are so rational and logical that any resourceful surgeon would be likely to conceive of and practice them; no doubt many surgeons have done so. It is a fact, nevertheless, that I have never happened to see all the successive steps in this method carried out elsewhere, and therefore I believe that it is worth while to recommend it as worthy of adoption as a routine measure unless some contraindication exists. As has been shown, the procedure appears to be attended by little risk, and its efficacy is attested by the fact that in the routine follow-up work of the Peter Bent Brigham Hospital, no instance of "recurrent" calculi is recorded among the patients that I have treated in this manner, although they may have occurred and the patients have gone elsewhere for relief.

# THE GROUPING AND TREATMENT OF ACUTE CEREBRAL TRAUMAS\*

CHARLES BAGLEY, JR.

In this paper I have made an effort to classify, according to clinical and postmortem observations, the large group of patients with lesions commonly spoken of as "fractured skulls." The early classifications were based chiefly on the type of bone lesion; the later studies were concerned chiefly with the degree of increased intracranial pressure. During recent years, the classification on the first basis has fallen into disuse in favor of that based on the degree of pressure and the accompanying neurologic symptoms. Dowman,<sup>1</sup> in classifying the cases, made use of both methods, and called attention to the importance of classifying the cases before determining the type of treatment.

Postmortem and experimental laboratory observations offer a basis for a classification which makes the determination of the type of treatment easier. My observations permit of a division into seven groups, the first two of which are designated according to the skull injury. The remaining groups are outlined according to the amount and location of blood within the cranial cavity.

Group I: Simple depressed fractures

Group II: Compound fractures, with or without depression

Group III: Extradural hemorrhage

Group IV: Blood overlying the cortex

Group V: Cortical injuries

(a) Cortical lacerations

(b) Diffuse superficial extravasations

(c) *Single or multiple cortical clots*

Group VI: Extravasations in the vein of Galen system

Group VII: Hemorrhage in the brain stem

The various groups have been found singly, but more than one type of lesion may be present in severely injured patients. For example, the classic middle meningeal hemorrhage may be associated with hemorrhage over the cortex due to a tear in the dura or to another lesion beneath an intact dura. Cases of simple injuries such as scalp lacerations and concussion are omitted, as these will fall, if the condition is complicated, into one of the foregoing groups.

## GROUP 1: SIMPLE DEPRESSED FRACTURES

The symptoms in this type of fracture vary greatly from those of slight concussion to severe compression, dependent on the degree of depression of the bone, the extent of brain injury beneath and the location of the depression. If the dura mater does not give way, the brain may be protected and extensive injury prevented, even if the fracture is severe. In other cases the force of the blow, usually from a blunt object, may entirely separate a portion of the skull, driving it through the dura into the cortex, causing bleeding which is apt to be serious if the break is in the region of one of the dural sinuses.

The common symptoms in the most simple depressions are those due to concussion plus a local headache and the signs of depression as determined by inspection, palpation and the roentgen examination. The surgical handling of these patients is important because though possibly only slightly injured, they must be subjected to operation for the purpose of investigating the brain injury, of relieving the cortex of the local pressure and of restoring a complete bony covering.

Elevation and replacement of the fragments as soon as the patient recovers from the immediate effect of the blow is the procedure of choice. This can best be accomplished through a curved incision skirting the rim of the defect, turning back a flap with the fragments attached to the under surface. If some of the fragments are found to have been separated from the pericranium, they should be replaced if possible beneath the flap. After elevation of the fragments the extent of the damage to the dura and cortex and the presence of blood must be determined. In many of the simple cases with the dura intact in which there is no evidence of underlying blood, incision of the dura is unnecessary. Others may require a small incision of the dura or the dura may be turned back in the form of a flap so that the injured cortex may be freed of extravasated blood. If this exploration reveals an increase of intracranial pressure and serious injury of the cortex sufficient to require decompression and drainage, this procedure had best be done separately through the subtemporal route where the defect can be adequately covered by temporal muscle.

Because of the absence of severe symptoms simple depressions may be overlooked until serious secondary symptoms ranging from headache to convulsive seizures occur. Swelling of the scalp or perhaps a small laceration may be the only local evidence of injury. This may persist for several days during which time the patient is discharged only to appear later with an evident depression and serious neurologic disturbances.

I had a good opportunity several months ago to examine the cortex in one of these unfortunate persons. The patient presented an inter-

esting problem because of the vague symptoms due to secondary cortical changes. The symptoms were much the same as those observed late in patients not having a depression of bone and frequently attributed to neurosis.<sup>2</sup> The patient was entirely incapacitated because of headache, dizziness, poor memory and a sense of numbness in the opposite arm. The presence of the depression, however, left no doubt in the minds of the insurance company or the physician as to the genuineness of the complaints, and the patient was sent in for operation. Elevation of the fragment at this late date, eleven months after the accident, was impossible, and yet it was very important not to leave this man with a depressed skull defect over the motor area. A small flap skirting the rim of the depressed area was carried through the periosteum, and with a thin chisel a plate of bone was removed with the flap. The remaining bony mass filling the defect was sacrificed and the flap replaced in the fashion of a bone graft. This, however, offered little relief from symptoms which were due to cortical changes. The incision, therefore, was extended downward into the temporal region and the usual subtemporal decompression done. When the dura was opened, the pia-arachnoid was thickened, and held firmly to the dura with adhesion in several places. Drains were placed beneath the dura, and there was free drainage of cerebrospinal fluid for several days. There was gradual improvement of symptoms over a period of seven months, and the man returned to work.

The symptoms in this case were due, no doubt, to a slight cortical injury with a small amount of blood overlying the adjacent cortex, the blood being more responsible for the anatomic and physiologic disturbance than the bone depression; for, as shown at operation, the meningeal changes extended well beyond the area of depression.

These meningeal changes with disturbance of cortical circulation producing vague symptoms may occur in trauma with associated cortical bleeding even without linear fractures. In another patient struck over the same region by a hammer, the early and late symptoms were much the same with complete incapacity to work after many months, due no doubt to a small amount of blood overlying the cortex followed by late meningeal and cortical changes. The absence of objective signs in this case created doubt as to the genuineness of this man's complaint, and the attitude of the insurance company in the two cases was entirely different, based, of course, in each case on the presence and absence of fracture.

---

2. Discussion of the late mental condition following trauma is not within the scope of this paper. This subject was discussed by Dr. Adolf Meyer. (*The Anatomical Facts and Clinical Varieties of Traumatic Insanity*, Am. J. Insan. 60: 373, 1904.)

GROUP II: COMPOUND FRACTURES, WITH OR WITHOUT  
DEPRESSION

In this group are included the patients with evident lesions of varying severity dependent largely on the amount of destruction of cerebral tissue and the extent of bleeding. The diagnosis is simple; early treatment is important for the relief from pressure due to bone fragments or blood clot and for the prevention of infection.

CASE 1.—*Compound depressed fracture, left frontal region. Immediate loss of consciousness with signs of increased intracranial pressure which rapidly cleared up after operation.*

H. R., aged 13 years, was admitted to the hospital after having been kicked in the left frontal region by a horse. On admission, there was free bleeding from the nose and projectile vomiting. The pulse rate was 53 per minute. In the left supra-orbital region there was a deep gash beneath which was seen depressed fragments of bone, blood clot and a small amount of brain tissue. Immediate operation consisted in raising the bone fragments, removing the blood clot and devitalized brain tissue, and repairing a small rent in the dura. At the completion of the operation, the pulse rate was 93 per minute. Consciousness returned promptly, and the wound healed per primam. Ten years have elapsed since the injury, and there has been no neurologic disturbance.

Serious early symptoms such as occurred in case 1 may lead to an early operation with complete restoration of function. On the contrary, the absence of early symptoms may result in delay with the onset of secondary symptoms as shown in case 2, in which the operation was delayed until the third day.

CASE 2.—*Depressed fracture in the right frontoparietal region by falling timber. Scalp wound on admission. Little attention paid to depression until the third day when there was paralysis of the opposite side of the body. Operation on the third day revealed a large amount of soft brain mixed with blood clot. Recovery of function. Epileptic seizures one year later.*

H. P., a married man, aged 54, was admitted to the hospital with the history of having been hit on the top of the head by a piece of timber which fell from a height of several feet. On admission, he was entirely conscious and answered questions intelligently. There was a large laceration of the scalp to the right of the midline extending into the parietal region. Beneath this, the bone was depressed. There was slight nausea and vomiting and some pain at the site of the lesion. The pulse rate and blood pressure were not disturbed, and little concern was felt for the patient until the gradually increasing paralysis of the left side progressed to a complete hemiplegia on the third day. Operation showed a large depressed fragment in the precentral area just in front of the motor cortex. When this was removed, there was a large amount of devitalized brain and blood clot which was removed by means of a catheter and syringe as described by Dr. Cushing.<sup>3</sup> Because of the late operation and the probability of infection, the detached bone fragment was not replaced and a depressed skull defect resulted.

---

3. Cushing, Harvey: Notes on Penetrating Wounds of the Brain, Brit. M. J. 1:221 (Feb. 23) 1918.

Following the operation, there was prompt improvement in the motor symptoms of the opposite side of the body. Five days after operation, the patient was able to raise the left arm over his head and to move the left leg. This prompt return led to the belief that the paralysis was due to edema posterior to the area of destruction in the brain rather than to active destruction of the motor cortex. When the patient was discharged from the hospital twenty-four days after operation, there was practically full return of muscle power. During the months following, he had some headache and dizziness, but returned to work seven months after the injury. He had a severe dizzy spell eight months after the injury and a general convulsion exactly one year after. The seizures were very troublesome and interfered with his work as foreman in construction work.

The delay in operation certainly caused an increase in the amount of brain destruction, and prevented the restoration of the bony covering, both of which factors perhaps increased the likelihood of post-traumatic epilepsy.

Even prompt operation may be of no avail in cases in which there is extensive destruction of brain tissue. In spite of early operation, these patients frequently have very rapid pulse and respiratory rates and elevation of temperature, and succumb within the first few days. In one of my patients in whom there was a large depressed fracture extending from the frontal into the parietal and occipital regions, thorough surface cleansing with control of superficial bleeding was undertaken immediately on admission; the following afternoon, the bone fragments were removed and the cortex freed of blood clot. The patient never regained consciousness and was very restless; his temperature gradually increased to 104 F., and the pulse and respiratory rates also increased until the fourth day, when he died.

In the remaining five groups the classification is based on the presence of blood within the cranium beginning with the most superficial hemorrhages in group 1 and taken in order from this to hemorrhage within the brain stem.

#### GROUP III: EXTRADURAL HEMORRHAGE

In all fractures of the skull there is, no doubt, some blood between the inner surface of the skull and the dura, but this is rarely of any consequence unless the middle meningeal artery or one of its large branches is torn. This lesion is usually associated with a fracture, not necessarily a large one, through the temporal bone crossing the course of the artery at a point where it is partly or entirely encased within the bone. The symptoms such as headache, vomiting, slowing of the pulse and respiratory rates, gradually increasing stupor, dilatation of the pupil on the side of the lesion, and late in the course, irritation, and still later, paralysis of the opposite side of the body, are due to the increase of general and local intracranial pressure. The original trauma is

generally not a severe one, and there is usually a latent period between the signs of concussion and compression—this period usually lasts from two to three hours, varying, of course, with the rapidity of the bleeding from the torn vessel. The early recovery from concussion gives one the impression that the injury is not a serious one, which impression has resulted in a fatality in many cases, the late symptoms going unrecognized until the onset of signs of severe compression.

As the condition cannot be recognized until the clot is of sufficient size to produce symptoms, extreme care must be exercised in cases of apparently slight injury, especially in the temporal or lower frontal regions, so that the first symptoms of compression will not be overlooked. Failure to recognize the symptoms will almost certainly mean a fatality, while prompt intervention early in the course of the symptoms is usually followed by prompt and complete recovery. In spite of frequent warnings, great embarrassment has been caused by the overlooking of this type of injury, and in my own experience, two men have been tried for murder because of an attack on persons who died later of unrecognized extradural hemorrhages. In one case, a soldier on guard duty at 4:30 in the afternoon rushed another soldier, striking his head against the wall of a room. As there were no symptoms at the time, the soldier completed his turn of duty and at 6 o'clock, when he was relieved, made no complaint. He was found unconscious in his quarters three hours later, and died five and one-half hours after the blow. At necropsy, a large extradural clot was found. The man who had attacked him was tried and sentenced to serve one year in the military prison.

In another man, case 3, the symptoms were thought to be due to intoxication, and operation was delayed until twenty-two and one-half hours after the onset. Figures 1 and 2 are photographs of the brain of this patient; the lateral view of the brain with the overlying dura shows the area which was covered by a large clot and also the site of the tear in the middle meningeal artery. The fracture at this point was a small stellate one without depression, the most anterior portion of which reached the meningeal artery tearing the vessel. The dorsal view shows the extent of compression of the hemisphere even after the removal of the clot.

*CASE 3.—Trauma, right temporal region at 2:30 a. m. Dazed for a few minutes but immediately afterwards drove his car home and retired as usual, even arranging his clothing. At 6 a. m. was restless and noisy. Gradual increase of symptoms. Operation at 1 a. m. the following morning. Death at 5 a. m.*

L. L., a married man, aged 38, was admitted to the hospital twenty-two and one-half hours after receiving a blow on the left side of the face which felled him. During the fall, he probably struck the right temporal region on the carpeted floor. After getting to his feet, he was dazed for a few minutes but walked the

short distance to his car, discussing the incident with a friend and the man who had struck him. As every one believed he was not hurt, the matter was treated lightly; he drove home, a distance of 1 mile, and retired at 3 a. m., after arranging his clothes as usual. Three hours later his wife, in an adjoining room, was awakened by the patient's loud breathing; she found him very restless and attributed his condition to alcohol. Five hours after the injury he was entirely unconscious, and there was twitching of the muscles of the left side of the body, the wife again thought this was due to alcohol. She did not call a physician for several hours, the physician arriving ten hours after the injury. The restlessness had ceased, and the patient was in coma which was interpreted as improvement; the seriousness of the condition was not recognized until six hours later, at which

Fig 1 (case 3).—Showing the type of hemorrhage found in patients included in group III. The lateral surface of the blood-stained dura shows the extent of an extradural clot; at A there is a rent in the middle meningeal artery, the clot extending backward from this point.

time he was sent to a hospital 100 miles away. On admission, he was unconscious; his temperature was 101 F., the pulse rate 128 per minute, and the breathing was labored, noisy and rapid. There was spastic paralysis of the left side of the body; the patient was rigid throughout and had a positive Babinski sign and ankle clonus on both sides. The pulse rate, in addition to being very fast, was irregular, and there was cyanosis. He was immediately taken to the operating room, and a right subtemporal decompression was done. A small fracture was found in the squamous portion of the bone, underneath which was a large blood clot, the extent of which is shown in figure 1. There was a small rent in the dura, and through this one could see that there was no bleeding beneath the dura. After removal of the clot,

the brain did not expand (fig. 2) and the dura remained depressed. The blood clot was firm and dark, and there evidently had been no bleeding for some hours. The symptoms were not improved, and the patient had two convulsions and died at 5 a. m.—twenty-six and one-half hours after the injury.

This fatality was obviously due to the long delay, resulting in serious compression of the medulla which had superseded the early symptoms of increased intracranial pressure.

Fig. 2 (case 3).—A dorsal view of the brain shown in figure 1. The marked depression of the cortex has persisted even though the overlying blood clot was removed three hours before death.

Case 4 illustrates two important points: first, the association of intradural with extradural hemorrhage, and second, the danger of lumbar puncture in cases of extradural hemorrhages.

*CASE 4.*—Admitted in a somewhat dazed condition immediately after a fall from a horse. Restless and disoriented five hours later. Marked increase of symptoms after lumbar puncture. Operation. Recovery.

E. L., aged 36, a schoolteacher, was admitted to the hospital with evidence of slight concussion within thirty minutes after falling from a horse. There was

bleeding from the right external auditory canal and contusion of the scalp above the right ear. The temperature was 98 F., the pulse rate 92 per minute and the blood pressure 104 systolic and 70 diastolic. Restlessness commenced two hours later and progressed steadily until five hours after the injury when the patient was entirely disoriented, extremely restless, and the pulse rate was 60 per minute. A diagnostic lumbar puncture was done, and very bloody cerebrospinal fluid was found.

Immediately following the lumbar puncture, however, there was marked increase in the symptoms with paralysis of the opposite side of the body and slowing of the pulse—a condition no doubt due to an increase in the amount of extradural bleeding as a result of lowered intracranial pressure. A right subtemporal decompression, six and one-half hours after the injury, showed a large amount of bright blood over the dura which was separated from the skull over a large area.

Control of the blood from the torn branches of the middle meningeal artery was simple enough, but the active bleeding from the denuded skull and dura was difficult to control, and transfusion was necessary. Unlike case 2, the brain lifted the dura against the skull, and bleeding was fairly well controlled. Because of the bloody cerebrospinal fluid, the dura was opened and a protective drain placed into the subdural space. The wound was closed. There was a severe reaction following the operation, the temperature rising to 104 F., and the pulse became very rapid. Within twelve hours, however, the patient was conscious, and the condition improved steadily until she was discharged from the hospital eighteen days after the operation. She resumed a part of her school work four weeks after the accident, and has remained well.

#### GROUP IV: BLOOD OVERLYING THE CORTEX

This is the most important of all groups because the greater number of cases fall into it and because of the importance of accurate diagnosis, so that one can determine the method of treatment, which varies according to the amount and distribution of blood and the time elapsing between the accident and the treatment.

Immediately after the accident, it is important to determine whether a clot is being formed or whether the blood is more or less evenly distributed throughout the cerebrospinal fluid space. The degree of richness of blood and cerebrospinal fluid has an important bearing on the symptomatology. If the blood is poured out in sufficient quantity over a short period, the major portion of it will accumulate and form a localized clot. In addition to the clot, however, some fluid escapes into the subarachnoid space, giving it a mixed symptomatology which makes the diagnosis of a clot difficult, especially in the absence of focal symptoms. Patients in this group present a grave appearance, with rapid, noisy breathing, low blood pressure and a pulse rate varying according to the predominance of the blood clot or free fluid. It is often difficult to determine whether immediate operation will stay the course, which is progressively downward. In general, it may be said that the patient will be benefited by the evacuation of a clot, preferably after the first six or twelve hours, but the course will be unfavorably

influenced if early operation is undertaken in the absence of a clot; e.g., where there is almost pure blood over the entire brain. If operation is performed in the early stage, the procedure in all probability encourages additional bleeding, and little can be accomplished in the drainage of pure blood. On the contrary, large quantities of richly mixed blood and cerebrospinal fluid will drain through a small rubber tissue wick. It is probable that the mixing of the blood and cerebrospinal fluid is responsible for the improvement following what may be called late drainage, from twenty-four to forty-eight hours after the injury, whether by lumbar puncture or craniotomy. Another factor in favor of late operation is the recovery from concussion, the adjustment of the brain to the altered conditions within the cranium and the lessening of general shock.

Early operation (i.e., within the first few hours) is, therefore, to be discouraged unless the signs, increased intracranial pressure and focal disturbance such as paralysis indicate that a clot is being formed. In some of the cases in which there is early evidence of a clot, immediate operation may be justified; especially is this true if the condition seems grave, indicating a fatal outcome. Immediate procedures in desperate cases are successful when the evacuation of an overlying cortical clot is possible, or when the blood is thoroughly mixed with cerebrospinal fluid. In the former condition, the opening in the skull must be made immediately over the clot, as a decompression not at the site of the lesion will obviously do harm; in the latter condition, the difficulty is due to an excess of fluid in the subarachnoid space, and the usual decompression and drainage suffices.

The former condition is well illustrated in the following case.

*CASE 5.—Admitted to hospital unconscious one hour after injury. Left hemiplegia. Immediate operation. Blood clot located over right hemisphere. Recovery.*

E. R., a man, aged 52, was admitted to the hospital one hour after being thrown from an automobile. His temperature on admission was 99.5 F., the pulse rate 80, and the respirations 24 per minute. The pulse was full and bounding, and the respirations labored and noisy. Immediately after the accident it was noted that though the right arm and leg were active, there was no motion in the left extremities. This condition also existed when he reached the hospital. It was concluded that there was a large hemorrhage over the right hemisphere, with free blood in the subarachnoid space. The condition seemed very grave. Immediate operation revealed a large amount of soft blood clot over the right hemisphere. This was removed, and richly mixed bloody cerebrospinal fluid flowed upward from the base. At the completion of the operation the pulse rate was 92; the respirations, 24 per minute, the temperature 102 F. and the blood pressure 165 systolic and 95 diastolic. Two days after the operation, the temperature was 100 F., the pulse rate 90, the blood pressure 130 systolic and 65 diastolic. The patient was able to move the left arm and leg. He was very irrational in the beginning; this condition was troublesome and still had not entirely cleared up on discharge from

the hospital, seventeen days after operation. At the time this paper was written, six months after operation, the condition of the patient was satisfactory except that he was emotional and tired easily, so that he was able to carry on only a part of his former duties.

This case is in sharp contrast to the type in which there is a slow bleeding over a hemisphere with definite signs of increased intracranial pressure with or without loss of consciousness. A characteristic case of this kind is seen in case 6.

*CASE 6.—Knocked to street by an automobile. Dazed when admitted. Slow pulse with severe headache. Operation on the third day revealed a small clot overlying the cortex. Recovery.*

W. H. C., a man, aged 66, was admitted to the hospital in a dazed condition immediately after having been knocked down by an automobile. When he reached the hospital, perhaps thirty minutes after the accident, he was dull, disoriented and complained of very severe headache. There was bleeding from the right nostril, ecchymosis of the right eyelid and a small scalp laceration in the right temporal region. The pulse rate on admission was 60, and the blood pressure was 148 systolic and 70 diastolic. The mental condition remained much the same during the first two days, but the headache increased so that it caused the patient to cry out. The pulse rate averaged 50 per minute during the second day. Because of the scalp wound near the right meningeal artery and the gradually increasing headache and the drop in pulse rate, the diagnosis of clot in the right fronto-temporal region, possibly extradural, was made. A right subtemporal decompression was done under local anesthesia, and a small fracture revealed in the temporal bone. There was no extradural bleeding, but a clot of moderate size overlying the cortex, covering chiefly the temporal and part of the frontal lobe, was found. As the greater bulk of the clot was at the base, it is probable that the blood originated from a torn vessel or a small tear in the cortex at the tip of the temporal lobe. There was marked increase of intracranial pressure, and the dark clot was partially squeezed out when the dura was opened. Removal of the clot entirely relieved the tension. Drains were inserted, and the wound was closed in the usual manner. During the first few days after the operation, the patient continued to be irrational and complained of a great deal of headache. There was gradual improvement, however; on the ninth day the temperature, the pulse and respiration rates were normal, and the general condition was satisfactory. The patient was discharged from the hospital on the twenty-first day after admission.

It is a matter of great importance to determine by clinical signs the presence of a clot of this sort and to undertake its removal as soon as the diagnosis can be made. As this clot was not sufficiently large to produce complete stupor and the lowest average pulse rate was 50 per minute, a slow, tedious recovery without operation was perhaps possible, in which case the clot would organize and no doubt produce late symptoms such as headache with a better chance of traumatic epilepsy. Figure 3 shows a portion of the dura with partially organized blood clot in a similar but more severely injured patient (case 12) in whose case

operation was not done and death occurred seven weeks after the injury.<sup>4</sup> Cases, therefore, in which there are rapidly forming blood clots, whether the clots are extradural or overlies the cortex, are extremely important in the early consideration of symptoms as prompt operation is necessary; if, however, the clot is small with slowly increasing symptoms, care must be taken to avoid overlooking it, as it may produce only borderline acute symptoms but very serious late symptoms.

Of even greater interest than the foregoing are cases in which the blood is thoroughly mixed with the cerebrospinal fluid. The explanation of a thorough mixture of blood and cerebrospinal fluid in one

Fig. 3 (case 12).—The dura covering the parietal lobe of the brain shown in figure 7. Partially organized blood clot is seen on the under surface of the dura; the condition also existed in the middle and anterior fossae.

case versus a local clot in another is to be found, no doubt, in the rate of bleeding dependent to a large extent on the amount of vascular injury. Patients with a slow diffusion of blood in the cerebrospinal fluid present a different appearance from those with a blood clot; the symptoms vary greatly according to the richness of blood in the cerebrospinal mixture. If the mixture is very rich, immediate symptoms are produced, while the late appearance of symptoms is characteristic in the case of thinly mixed fluid.

4. Death, however, was not due directly to the head injury, but to a ruptured pelvic abscess which was overlooked because of the patient's stupor.

The effect of blood in the cerebrospinal fluid was studied experimentally and the results of the experiments published in the *ARCHIVES OF SURGERY*, July, 1928.<sup>5</sup> Eighteen adult dogs and twenty-six puppies (five litters), all less than 10 days old, were given injections of whole blood taken from the longitudinal sinus of the pups and from the veins in the legs of adult dogs. Free mixture of the blood and cerebrospinal fluid was desired, and the blood was slowly injected into the cisterna magna or into the subarachnoid space over the cerebral hemisphere and, in a few instances, into the cerebral ventricles. The quantity injected varied from 0.5 to 5 cc. of blood. Immediately after the injection, the animals were spastic and recovered from the narcosis slowly. In the adult dogs, the injections were frequently followed by convulsive seizures with frothing at the mouth. The injections were repeated in the dogs at intervals of a few days, and many of them died during the first few days of the course. They were hypersensitive and irritable, and the nutrition was poor. The most striking course was seen in the general behavior, diminished activity and poor development of the younger dogs, so that the pups which were given injections could easily be distinguished from the controls. Late in the course, when the pups were half grown, four of them died in status epilepticus.

The conclusions following the study were as follows:

*Blood mixed with the cerebrospinal fluid of young and adult dogs produces neurologic disturbance varying from slight difference in behavior to severe convulsive seizures. Though some of the animals were severely affected by small quantities of blood mixed with the cerebrospinal fluid, others have survived more than a year, and are apparently normal.*

*Following the introduction of blood into the cerebrospinal fluid, there begins a reaction of the parts of the meninges which have come in contact with the blood. The meningeal reaction tends to subside and may disappear as the blood disappears from the fluid. After several weeks, the cell elements are less numerous in the meninges, but a large amount of fibrous tissue is present.*

*Late in the course of the meningeal reaction, changes in the structure of the cortex are observed.*

*Moderate dilatation of the ventricle not infrequently occurs following the introduction of blood into the cerebrospinal fluid of young pups. The condition may occur in adult dogs, but with less frequency.*

The most important acute change is the meningeal reaction or the production of sterile meningitis, an illustration of which is shown in figure 4.

In considering the symptomatology of patients of this group, one must not lose sight of the fact that the blood is mixed with cerebrospinal fluid, a most important process from the standpoint of progress,

---

5. Bagley, Charles, Jr.: *Blood in the Cerebrospinal Fluid: Resultant Functional and Organic Alterations in the Central Nervous System*, *Arch. Surg.* **17**:18 (July) 1928.

Fig. 4.—A section taken from the base of an adult dog which received four injections of blood from 1 to 1.5 cc. in amount into the cisterna magna over a period of seventeen days. The animal was killed two days after the last injection. The meninges were thickened and the seat of active cell proliferation.

the mixture even though rich, producing a substance that can be drained with improvement of symptoms in sharp contrast to the patient with pure blood throughout the subarachnoid space in which drainage is usually followed by a fatality. Experience has shown that the patient in this type of case does better if drainage is not attempted until some hours after the accident. There are several reasons why this delay is beneficial, but time for allowance of mixture of the blood and cerebrospinal fluid is no doubt an important one. After this mixture takes place, the immediate symptoms will depend, as in the dogs, on the amount of fluid in the subarachnoid space. The amount of bloody fluid may be of sufficient quantity to produce symptoms which must be differentiated from those due to blood clot. In general, the pulse and respiratory rates are quick, and the patient is irritable and restless rather than stupid. He may even be fully conscious. The type of headache complained of is different from that complained of when there is a clot, as it is more sharp and stabbing, and the vomiting associated with severe pressure is likely to be absent. In the severe case, early operation may be necessary to ward off a fatal issue. If, in spite of the lapse of several hours, when the patient should have recovered from an ordinary concussion syndrome, there is marked circulatory and respiratory embarrassment, a prompt decompression with drainage may be indicated. A patient of this type is seen in case 7.

*CASE 7.—Admitted immediately after injury. Unconscious. Pulse rate, temperature and respiration rate not greatly disturbed. Fourteen hours after admission breathing labored, deep cyanosis. Decompression and drainage. Recovery.*

P. J., a married man, aged 50, entered the hospital within an hour after falling in an aeroplane. There was bleeding from the right external auditory canal. There was a dislocation of the right cranioclavicular articulation and several superficial abrasions over the extremities. During the first twelve hours after admission, the pulse ranged from 96 to 104 per minute, the respirations from 24 to 30 and the temperature from 99 to 99.8 F. The breathing was very noisy, and there was no indication of returning consciousness. During the thirteenth hour after admission, the patient became very restless and the breathing more labored, with definite cyanosis. This increased during the fourteenth hour, when the cyanosis was marked and breathing very labored. The pulse rate was 130 per minute, and the respiratory rate varied from 10 to 30 per minute. It was evident that nothing was to be gained by further waiting, though any operative procedure offered little because of the severe cardiorespiratory upset. A right subtemporal decompression without anesthesia revealed a stellate fracture of the squamous portion of the temporal bone. When the dura was exposed, it was very tense, and when incised, a large amount of very bloody cerebrospinal fluid escaped. The tension was then entirely relieved, a rubber tissue drain inserted and the wound hurriedly closed. There was improvement in the respirations immediately after the evacuation of the bloody fluid, but the cyanosis remained, gradually clearing up over the next six hour period, when the patient showed some signs of consciousness. The blood pressure on admission was 140 systolic and 80 diastolic; immediately before the operation it was 120 systolic and 35 diastolic, and six hours after the operation,

Fig. 5 (case 10).—Reading from left, the tubes show the fluid obtained on lumbar puncture forty hours, sixty-four hours, five days and nine days after the accident.

130 systolic and 70 diastolic. During the first four days after operation, there was marked improvement; the patient was almost fully conscious and fairly well oriented.

Five days after the operation, there was extreme restlessness, slight elevation of temperature, of pulse and respiration rates, and râles were heard at the base of the left lung. On the following day there was consolidation of the base of the left lung, and the temperature rose to 101 F. by axilla, the pulse rate to 100, and respirations to 34. Restlessness at this time was very troublesome. There had been very free drainage of cerebrospinal fluid, the bloody content of which had gradually diminished until it was now only slightly yellow and the drains were removed. On the following day, the temperature was 102.6 F. by axilla. From this time the problem was chiefly a medical one, the pneumonia a few days later involving the right lung. The temperature did not return to normal until the thirty-fourth day. During this period, the restlessness was very troublesome, the patient being entirely disoriented even until the date of discharge forty-three days after the accident. There was gradual improvement in the condition until two and one half months after the accident, when the patient resumed light duty.

The source of the blood is of little consequence, the symptoms varying according to the amount rather than to the place of bleeding. Fractures of the base are serious lesions because these patients have a large amount of blood in the cerebrospinal fluid or perhaps pure blood throughout the subarachnoid space. The mortality rate in this type of case in the first few hours following the accident is high, but if the patient survives the first twenty-four hour period, a diagnostic puncture will frequently show that mixture of the blood and cerebrospinal fluid is taking place. In this early period, the mixture will be red, and some slight improvement of the symptoms may follow even though only a small amount of fluid be removed. The improvement usually lasts from twelve to twenty-four hours when another lumbar puncture is indicated. If improvement follows the second lumbar puncture, it is generally safe to conclude that the patient can be treated by means of repeated lumbar punctures. Three or four days after the accident, the fluid is no longer bright red but has a brownish tint rapidly passing to a deep, then faint yellow. The improvement of symptoms almost always follows the change in color of the fluid (fig. 5).

If the diagnostic lumbar puncture shows thick blood, there is little likelihood of improvement after the puncture and further punctures are not advisable; one must then make a choice between a decompression and lumbar puncture at a later date, i.e., after the patient has accomplished some mixing of the blood and cerebrospinal fluid, or trust to general treatment.

At this point mention should be made of the general handling of all cases of serious cerebral trauma. General shock is a very serious condition and must be combated by the usual measures. One must avoid restraint such as strait-jackets, and use coal tar products and bromide rather than morphine for the control of restlessness and delirium.

Hypertonic salt solution has its place, but in general, the effect of free purgation following the administration by mouth of large doses of magnesium sulphate is more satisfactory. The position of the patient is important. If restlessness permits, the most favorable position is on the side with the head of the bed elevated and the patient's head placed in a position which will allow mucus and saliva or blood and cerebrospinal fluid to flow outward rather than into the pharynx.

The following case illustrates the effectiveness of lumbar puncture.

*CASE 8.—Injured by falling backward and striking occipital region. Evidence of severe concussion in first twelve hours with more serious symptoms in second twelve hour period. Lumbar puncture twenty-two hours after accident revealed very bloody cerebrospinal fluid; second puncture; twelve hours later, fluid less blood-tinged. Four lumbar punctures. Complete recovery.*

M. H., aged 5 years, was admitted to the hospital in a semiconscious condition after falling backward, striking the occipital region on a concrete pavement. The patient vomited several times during the first few hours and complained of headache. On admission, the temperature was 99.4 F., the pulse rate 140 and the respirations 32 per minute. Examination revealed a large edematous area over the left occipitoparietal region. On the second day after admission, nausea was troublesome, and there was severe headache; a lumbar puncture twenty-two hours after the accident revealed very richly mixed blood and cerebrospinal fluid. Following the puncture, the condition was slightly improved for ten hours, when the delirium was worse, and the child seemed to be suffering greatly. A lumbar puncture done twelve hours after the first one showed the fluid to be much clearer. The next day the child was more comfortable with improvement in the mental state, temperature, pulse and respiration rates. On the fifth day, she complained of being chilly. The temperature at that time was 101 F. Examination of the chest revealed râles over both sides and the upset was attributed to bronchitis. On the seventh day, the temperature was again normal and she was more comfortable. On the ninth day, a lumbar puncture showed the fluid dark yellow tinged. There was still some headache and occasional vomiting, but the mental condition was clear. From this day until the seventeenth day when she was discharged, there was a gradual improvement of symptoms, and further lumbar punctures were not done. The child was examined a month after discharge and found to be entirely normal.

The next case illustrates what may happen in patients if the bloody cerebrospinal fluid is not removed by lumbar puncture or craniotomy. A section of the brain shown in figure 6 also shows the source of bleeding. The blood in this case escaped from a cortical vein torn at the site of its entrance into the dura near the longitudinal sinus and represents a common lesion following trauma.

*CASE 9.—Small amount of blood in the cerebrospinal fluid following cerebral trauma. Death in status epilepticus on the third day.*

J. D., aged 6 months, was in excellent physical condition when left with a colored nurse. When the mother returned two hours later, the child was unconscious and the nurse did not give any indication of the cause. Twenty-four hours later the fontanel was tight, and there was a general convulsive seizure. Seizures occurred at short intervals until collapse eighty hours after the onset, when the child

died. Lumbar puncture during the third day revealed bloody cerebrospinal fluid, and a long journey to the hospital was started. On arrival, twelve hours later, the child was in collapse and died within an hour.

Necropsy showed a moderate amount of blood mixed with the cerebrospinal fluid and a small blood clot over the left frontal cortex where a vein had been torn from the dura (fig. 6). The pia-arachnoid was thickened and the veins moderately dilated.

Early lumbar punctures in case 9 would have prevented or certainly have lessened the severity of the convulsive seizures which were the cause of the fatality.

Fig. 6 (case 9).—Illustrating group IV. A small clot is seen at A. The clot marks the source of blood which escaped into the cerebrospinal fluid, resulting in death on the third day after the accident. Death followed a forty-eight hour period of convulsive seizures.

The following case illustrates the range of pressure and variation in color of the cerebrospinal fluid in a patient with mild symptoms.

CASE 10—Admitted immediately after falling from a second story window. Dull but answered questions. The following day slight increase of stupor with quickening of the pulse rate. Bloody fluid on lumbar puncture. Recovery.

K. G., a schoolboy, aged 11, was admitted to the hospital in a dazed state. According to the history, he had fallen from a second story window and was unconscious for a few minutes. Examination on admission showed a scalp laceration 1.5 cm in length over the occipital region. The pupils were contracted

Blood pressure was 88 systolic and 46 diastolic, temperature 99 F. and the pulse rate 82. He vomited several times. During the first twenty-four hour period the pulse averaged 84 and the highest temperature was 100 F. The patient was dull but responded to questions. When examined forty hours after the accident, the stupor had increased, but the patient could be aroused. However, he did not cooperate in the examination. There was slight postcervical rigidity and a positive Kernig sign on both sides. Lumbar puncture at this time revealed a bright red cerebrospinal fluid of thin consistency; the cerebrospinal fluid pressure was 290 mm. of water. There was some improvement following this puncture. In order to free the subarachnoid space of bloody cerebrospinal fluid, a lumbar puncture was done twenty-four hours later. The pressure at this time was 240 mm. of water. A third puncture was done five days later, when the pressure was 190 mm. of water. After an interval of four days, another puncture was done with a pressure reading of 180 mm. of water. A final puncture was done nineteen days after admission, and the spinal pressure was 155 mm. of water. Figure 5 shows the color of the fluid as obtained on the first four punctures.

The early symptoms in the foregoing case were not severe but progressive, so that if the patient had been allowed to go untreated for several days the symptoms would have become more serious. The patient in the following case had a mild early course, and at the end of a week presented symptoms which, because of his age and advanced arteriosclerosis, were thought to indicate the beginning of pneumonia.

*CASE 11.—Dazed when admitted immediately after an accident. Pulse rate on admission 84 per minute. Irrational for short periods on third day, and occasionally complained of headache. Sharp rise of temperature on sixth day with slowing of pulse rate and very troublesome mental confusion. Repeated lumbar punctures beginning on the seventh day. Recovery.*

M. H. A., a married man, aged 69, was admitted to the hospital in a dazed condition; he did not know how he had been injured. Examination revealed a laceration over the right frontal area of the scalp and extensive bleeding from the nares. On admission, the pulse rate was 84 per minute and the temperature was 98 F. Roentgen examination revealed a right cranioclavicular dislocation, but no fracture of the skull. The patient was nauseated, but did not vomit. A few hours after admission, the temperature was 100.4 F. Blood pressure on admission was 150 systolic and 85 diastolic; on the second day, it was 125 systolic and 85 diastolic. On the third day, the patient was irrational for short periods and complained of occasional headache. On the sixth day, the temperature gradually rose to 102 F., while the pulse rate dropped to 65 per minute. On the seventh day, the patient was confused and gave every appearance of being seriously ill. There was slight postcervical rigidity and a positive Kernig sign on both sides. Examination of the fundus showed a well marked edema of the disks, and this with the slow pulse rate indicated a gradual increase of intracranial pressure. Early lumbar puncture would have prevented what was now evidently an advanced stage of meningeal irritation with beginning cerebral edema. Lumbar puncture at this late stage was of questionable value, and the operation of choice would have been a subtemporal decompression with drainage. This, however, seemed a rather foolish undertaking in this case because of the impression of a cardiorespiratory break and a diagnostic lumbar puncture was advised. A small amount, 6 cc., of very dark brown cerebrospinal fluid was withdrawn. Several hours afterward, the patient was com-

fortable and more alert, the temperature ranging from 100 to 101 F. On the eighth day another puncture was done, and again blood-stained fluid was found; the temperature ranged from 99 to 100 F. On the ninth day, a third puncture was done showing deep yellow-tinged fluid, and following this he slept for several hours. The highest temperature was 99.3 F. Following the second puncture, the pulse rate ranged between 80 and 90 per minute. On the eleventh day, the patient was well oriented and complained of severe headache. A lumbar puncture at this time revealed yellow-tinged cerebrospinal fluid. Another lumbar puncture on the thirteenth day revealed clear fluid. From this point on there was gradual improvement of neurologic symptoms until discharge on the twenty-second day. Marked dyspnea and sharp precordial pains were present on the thirteenth day, due to the cardiac strain, but this condition gradually cleared up along with the neurologic symptoms until the time of discharge.

Improvement does not always follow lumbar puncture in the late course and the procedure must be checked with care to determine the immediate effect of the puncture, for example, if a small amount of fluid is withdrawn and there is improvement in the first few hours, the puncture may be repeated, the subsequent symptoms being taken as a guide for or against additional punctures.

In a previous report,<sup>6</sup> the ill effect of late lumbar puncture is discussed. In case 18, page 58, in that report, the symptoms appeared at the end of the first week. The patient was not admitted to the hospital until the fourteenth day, when the pulse rate was 60; there was delirium, postcervical rigidity, a positive Kernig sign, headache and beginning choking. Lumbar puncture revealed yellow cerebrospinal fluid. Three punctures were done at intervals of from six to twenty-four hours; the first puncture seemed to give some relief for a short period, and the symptoms increased after the second puncture. Forty-eight hours after admission, the symptoms were very severe, and a right subtemporal decompression was done. Only a small amount of fluid was found in the subarachnoid space, the condition having reached a stage of cerebral edema. Following the operation, there was only scant drainage of cerebrospinal fluid, and the condition grew worse until death occurred four days later. Necropsy showed a marked degree of meningeal thickening with cell infiltration.

If one is convinced of the irritating effect of blood in the cerebrospinal fluid and not misled by the fact that in some cases the blood may be absorbed and do no apparent harm, he will endeavor to learn early in the course of treatment for cerebral trauma whether or not there is blood in the cerebrospinal fluid, and if it is present, to accomplish its removal early by the most simple method applicable to the case. The method employed will depend on the amount of blood present and the symptoms produced. That the patient is capable of removing a certain

---

6. Bagley, Charles, Jr.: *Blood in the Cerebrospinal Fluid: B. Clinical Data*, Arch. Surg. **17:39** (July) 1928.

amount of blood from the fluid there can be no doubt, nor can there be any doubt that this spontaneous removal of the blood is greatly aided by mechanical drainage. The improvement which follows the removal of a few cubic centimeters of bloody fluid in favorable cases seems entirely out of proportion to the amount of fluid removed, a fact which seems to indicate that the absorption on the part of the patient is aided by the mechanical removal.

#### GROUP V: CORTICAL INJURIES

Small cortical lacerations no doubt occur in many cases of group 4, but are unimportant further than as the starting point of bleeding. In the cases in this group there is sufficient cortical destruction to produce general disturbance in silent areas and focal disturbance in active areas.

(a) *Cortical Lacerations.*—Lacerations of the cortex may result from the direct force of the blow and be associated with simple or compound fractures of the skull. The management of these lesions has been discussed under the headings of groups I and II. Lesions of this type frequently occur, however, without fracture of the skull. The tips of the temporal and bases of the frontal lobes are most often the site of injury which may, however, occur in any part of the cortex.

The symptoms are indefinite unless the lesion is in an active area with definite focal disturbance. When the lesion is in a silent area, the diagnosis depends on the signs and symptoms of increased intracranial pressure resulting from the edema at the site of the laceration and a filmlike blood clot which usually spreads over the cortex.

In every extensive laceration sometimes involving both temporal and frontal lobes, operative procedures are of little avail, but in the milder cases a craniotomy should be done at or near the site of laceration as a great deal can be accomplished. The patients in two recent cases presented almost identical symptoms of gradually increasing intracranial pressure over a period of four days following injuries in the right temporofrontal region. In each case a right subtemporal decompression was done, and a small amount of dark clotted blood was found over the lateral surface of the hemisphere extending to the base, where a larger amount of the same substance was found. In these cases it was concluded that the blood originated from the laceration at the tip of the temporal lobe. Both patients made satisfactory recoveries.

The brain of a patient with a cortical laceration obtained seven weeks after the injury is shown in figure 7. The surgeon in charge of this patient did not operate as he was unable to localize the lesion, and he believed the progress, though slow, would eventually lead to recovery. Because of the stupor, a pelvic inflammatory condition was overlooked, and the patient died of peritonitis after an illness of seven weeks.

CASE 12.—*Injured by falling from motorcycle. Stormy course without operation over a period of seven weeks. Patient still in coma. Death due to ruptured pelvic abscess.*

F. McM., a girl, aged 16, was admitted to the hospital in an unconscious condition immediately after a fall from a motorcycle. On admission, there was a deep laceration of the left temporoparietal region extending to the skull, bleeding from the nares, paralysis of the right internal rectus and sluggish right pupil. The pulse rate was 60, the blood pressure 136 systolic and 80 diastolic, the temperature 98 F. and the respirations free and easy. A roentgenogram did not reveal a fracture of

Fig. 7 (case 12).—Illustrating group V, *a*. Extensive laceration of the cortex of the left temporal lobe. The patient was not operated on, was in semistupor for several weeks, during the seventh week developed peritonitis secondary to pelvic inflammatory condition which had been overlooked, and died within a few days.

the skull. On the second day, the blood pressure was 138 systolic and 80 diastolic. During the first days the patient was dull, but answered questions correctly at times. During the weeks that followed, the course was tedious but not considered hopeless. I first saw the patient seven weeks after admission because there had been troublesome vomiting, and a sharp rise of temperature and some further cranial complication was feared. At this time she was in coma and there was marked rigidity of the abdomen, with leukocytosis. Palpation of the abdomen

disturbed the patient. Laparotomy revealed extensive peritonitis secondary to a pelvic inflammatory condition. The inflammatory pelvic condition had been overlooked because of the coma, and the abscess had ruptured. Death occurred the following morning.

The necropsy was interesting, as it furnished a brain with a cortical laceration and small blood clot (figs. 3 and 7) seven weeks after the occurrence of the injury. If recovery had occurred, it would certainly have been very tedious and the ultimate outcome poor. An early

Fig. 8.—Illustrating group V, *b*. Extensive hemorrhagic extravasation in the pia-arachnoid associated with the formation of small cortical clots in the right hemisphere and laceration and large cortical clots in the left hemisphere shown in figure 11.

decompression was indicated by the evidence of pressure and the slow progress of symptoms as set forth in the previous part of the paper under the head of "Blood Clot."

(*b*) *Diffuse Superficial Extravasations.*—Under this subheading I shall discuss a condition in which the cortex over a large area is very dark because of the diffusion of pure blood which cannot be washed out

Fig. 9.—Section taken from the right hemisphere of figure 8, showing the mass of blood in the pia-arachnoid mesh.

Fig. 10.—Illustrating group V, *b*. Section of cortex shown in figure 8, underlying blood-stained pia-arachnoid, showing vascular distortion and extravasation of blood.

or otherwise mechanically removed. The condition may involve the cortex of an entire hemisphere as shown in figure 8 without the presence of gross lacerations. In figure 9 the location of the blood is shown to be almost entirely within the pia-arachnoid mesh, even the superficial layer of the cortex remaining unstained with only a few pigmented cells, showing in the zonal layer. The recognition of the condition is important as it indicates a serious general upset characterized particularly by delirium which may last for many weeks. I have encountered the condition several times in craniotomies following traumas. When it has been very extensive, the cases have ended fatally, and in cases in which there has been recovery the patient has been disoriented long after the signs of increased intracranial pressure have disappeared. The explanation of the long-continued upset is to be found no doubt in the disturbances of cortical circulation ranging from stasis to actual rupture of vessels and the extravasation of blood as shown in figure 10 which is a photomicrograph of the cortex underlying the dark blood-stained meninges.

*CASE 13.—Patient in a very serious condition on admission, immediately after automobile accident. Right subtemporal decompression. Large amount of bloody cerebrospinal fluid and very dark blood-stained cortex. Tedious recovery.*

A. C., a woman, aged 68, was admitted to the hospital immediately after having been knocked to the street by an automobile. She was wildly delirious, with a pulse rate of 60 per minute and a respiratory rate of 20. A right subtemporal decompression revealed a large amount of bloody cerebrospinal fluid and a black-looking cortex. Drains were inserted and the pressure symptoms entirely disappeared, but the patient continued to be delirious over a period of weeks. During this time she had a rather extensive bronchial pneumonia, from which she recovered. The active delirium lasted three weeks, but she was not entirely oriented until six months after the operation, at which time she took up her household duties and has been fairly capable since.

(c) *Single or Multiple Clots.*—Clots of varying size may be found in almost any part of the cortex, at times immediately underlying the point of trauma or as the result of the force of the blow at a point far removed from the external area of trauma. In the former instance, the clots are often multiple and difficult to locate, and in addition to the clot, cortical lacerations may be present; in the latter case, localization is less difficult, and a single clot is the common occurrence. The symptoms depend on the area of cortex involved, the number and size of the clots and the presence or absence of associated lesions, such as cortical lacerations or free blood overlying the cortex.

The severely injured patient usually succumbs within the first twenty-four hour period, and operative treatment accomplishes very little. A cross-section of the brain shown in figure 8 with a large and several small clots within the cortex of the left hemisphere is shown in figure 11.

There was also a large laceration of the left temporal lobe. On admission, the condition was grave and an immediate decompression was done. A large amount of free and clotted blood was removed without improvement of symptoms. The patient died eighteen hours after admission. Single clots with less severe initial disturbance cause gradually increasing general and focal signs and symptoms and constitute one of the most favorable groups for radical operative procedures. Localization of the clot is important since the purpose of treatment is the removal of the clot and not merely the relief from pressure by means of decompression. The removal is important for relief from the early symptoms.

Fig. 11.—Illustrating group V, *c*. A large and several small clots occur at *A* and *B*. Many superficial clots of this type were present throughout the left hemisphere of this brain. The left temporal lobe was severely lacerated. (Same brain at figure 8.)

A craniotomy at any point other than the site of the clot is harmful as it causes distortion of the tissues between the blood clot and the operative field. Complete removal of the clot avoids additional destruction of the cortex through softening. The following case in which there was a clot in the lower motor area of the left hemisphere with complete loss of speech illustrates the importance of uncovering the area involved so that the clot may be easily removed and the complete recovery of this important area made possible.

*CASE 14.—Admitted to hospital five days after having been hit by a baseball on the left side of the head. Aphasia. Weakness of the right side of face. Operation: left osteoplastic flap and decompression at base. Recovery.*

W. F., a professional baseball player, aged 23, was admitted to the hospital five days after having been hit on the left side of the head by a baseball. Loss of speech came on about fifteen hours afterward, and during the first twenty-four hours there was considerable nausea and vomiting, but very little headache. There was no mental disturbance. The pulse rate on admission was 44, and the blood pressure 115 systolic and 78 diastolic. There was definite weakness on the right side of the face, which did not involve the upper portion, and complete aphasia. The reflexes were definitely greater on the right than on the left side. The day after admission, he complained of headache, numbness and tingling in the right hand, and there was twitching of the tongue. Two days after admission, a left osteoplastic bone flap was done with a decompression at the base. When the flap was elevated, about a teaspoonful of old extradural clot was found. Along the anterior limb of the flap, a small fracture was found, extending from the frontoparietal region downward and backward. There was sufficient tension below the dura to cause it to bulge in a domelike fashion. The dura was then opened opposite the bulging portion, and the brain showed a moderate increase of pressure. There was a small rent in the pia-arachnoid over the lower motor area. When this rent was completely uncovered a large clot was slowly extruded entirely relieving the tension. The cavity was gently washed out and the fragments of pia-arachnoid replaced over the rent and the dura and flap replaced. A very small decompression was made at the base of the flap and a small rubber tissue drain placed over the cortex. This was done to permit a thorough cleansing of the blood-stained tissue. The day after operation, the pulse rate ranged between 54 and 104. On the third day, the patient spoke several words. The condition gradually improved, so that on the thirteenth day he was walking around; when discharged on the twenty-fifth day, the condition was entirely satisfactory with very little disturbance of speech, and normal muscle power. He returned to his profession as a baseball player and has continued this during the eight years since the accident.

This case is included to show the necessity of radical procedures in cases of this type. A lumbar puncture would obviously have done harm, and decompression on either side would not have allowed the clot to escape; if it had been done on the left side, there would have been a marked bulging of the temporal lobe and greater destruction of the area involved.

The fact that single cortical clots occur in the neighborhood of the injury makes it important to expose the cortex as near the point of external injury as possible. It must be remembered, however, that subtemporal decompression as originally practiced by Dr. Cushing is limited to the area of the skull covered by the temporal muscle, and that the sacrifice of bone in this area is compensated for by the carefully preserved muscle. When other than the cortex of the temporal lobe is to be exposed, therefore, an osteoplastic bone flap must be used, for in this there is no sacrifice of bone, the bony wall being completely restored.

In the following case, the patient received an injury in the right temporal region. The operation revealed a large blood clot in the right temporal cortex, with considerable blood overlying the surrounding cortex.

CASE 15.—*Injured in falling from a stairway. Fairly satisfactory course for four days, then evidence of increased pressure. Right subtemporal decompression, removal of right temporal lobe blood clot. Drainage. Recovery.*

W. D., a man, aged 56, was admitted to the hospital in a semiconscious condition after falling from a stairway he was repairing. When admitted, there was a contusion of the scalp in the right temporal area; the pulse rate was 82, the temperature 97 F. and the respiratory rate 22. Bloody cerebrospinal fluid was draining from the right ear. The pupils were dilated, and the knee jerks were hyperactive. On the day after admission, the pulse was normal. The patient was irrational and complained of headache. The drainage of cerebrospinal fluid and bleeding from the right ear continued for forty-eight hours, a condition no doubt responsible for some improvement during this period. Four days after admission, there was a slight internal squint of the left eye. The blood pressure was 138 systolic and 64 diastolic, and the pulse rate 60 per minute. On the fifth day, the patient was dull and suffering from severe headache; the pulse rate was 58, and the respirations 28 per minute. A right subtemporal decompression was done. When the dura was incised, there was some blood overlying the cortex. When this was removed, the cortex was bulging greatly. Beneath a small rent in the pia there was a large blood clot which was extruded through the slightly enlarged pial tear. The cavity and overlying cortex were washed with salt solution, and drains were inserted. Six hours after the operation, the pulse rate was 90. All signs of increased intracranial pressure were absent, and there was gradual improvement in the mental condition. The patient was discharged on the twenty-eighth day after admission. It is now four months since the operation; there is deafness of the right ear with dizziness, but the patient has returned to light duty.

#### GROUP VI: EXTRAVASATION IN THE VEIN OF GALEN SYSTEM

Cases of this type were the subject of a report from this laboratory in 1923.<sup>7</sup> Three fatal cases, with necropsy observations in two, were reported. The lesions in the two brains examined were almost identical; there were numerous hemorrhages in the structures anatomically related to the vein of Galen and its tributaries. The symptomatology was characterized by an early sharp rise of temperature and rapid respiratory and pulse rates, all of which continued throughout the course. Muscle power was affected to a greater or less degree, the disturbance being chiefly of the spastic type with predominance of loss of power on one side, and the deep reflexes were increased. The intracranial tension was low, and the cerebrospinal fluid contained a small amount of blood. The state of consciousness in the beginning suggested simple concussion; later the patients were restless, coma ensuing toward the end of the

7. Bagley, Charles, Jr.: Extensive Hemorrhagic Extravasation from Venous System of Galen, with Clinical Syndrome, Arch. Surg. 7:237 (Sept.) 1923.

course. This type of lesion is an infrequent one, and since the report in 1923, I have had one fatal case in which the diagnosis was verified and two cases with recovery in which the symptoms were characteristic, the course tedious and recovery incomplete.

*CASE 16.*—Injured in an automobile accident. Pulse rate on admission immediately after accident, 120 per minute; temperature, 101.5 F.; well marked spasticity of extremities, more on right. Thirty-four hours after admission, temperature 106.5 F. Death fifty-three hours after admission.

M. L., a married woman, aged 21, was admitted to the hospital in an unconscious condition after an automobile accident. On admission, the pulse rate was 120, the temperature 101.5 F., the respiratory rate 24 and the blood pressure 110 systolic and 60 diastolic. There was a laceration on the left side of the lip and a contu-

Fig 12 (case 16) —Illustrating group VI. The figure on the left shows a block from the brain of a case previously described (*Arch. Surg.* 7:237 [Sept.] 1923), showing extensive hemorrhagic extravasation in the corpus callosum, characteristic of lesions secondary to vein of Galen injuries. The figure on the right shows a block from a recent case clinically placed in group VI, with hemorrhagic extravasation at *A* and *B*

sion under the left eye. There was well marked spasticity of the extremities, more on the right side. She moved the arms freely and picked at the bedclothing. The pupils were normal. Five hours after admission the pulse rate rose to 158, the blood pressure 135 systolic and 60 diastolic and the respiratory rate to 56 per minute. There was considerable twitching of the muscles of all extremities. On the day after admission, except for the high temperature and rapid pulse and respiratory rates, the patient did not seem to be seriously ill. At this time she seemed conscious of her surroundings, and members of her family thought she recognized them. The temperature ranged slightly above 101 F., the pulse rate from 130 to 135 and the respiratory rate from 28 to 40 per minute. The patient was rather rigid with increase of the deep reflexes and a positive Babinski sign

on the right. Lumbar puncture revealed slightly blood-stained cerebrospinal fluid under low pressure. A tentative diagnosis of injury to the vein of Galen was made, and operation was not recommended. Thirty-four hours after admission, the temperature registered 106.5 F. by rectum, the pulse rate 160 and the respiratory rate 58 per minute. At this time the diagnosis was definitely made. The pulse rate and temperature remained high, and the patient died fifty-three hours after admission.

Necropsy showed nothing abnormal on the external surface of the brain. The characteristic lesions in the structures throughout the vein of Galen area and the close similarity to the lesions in one of the previously described cases is shown in figure 12.

The following case history is included because the patient presented symptoms of the fatal cases but ultimately recovered.

*CASE 17.—Injured in automobile accident. Temperature, 106 F.; pulse rate, 160 nine hours later. Bilateral motor disturbance with spastic hemiplegia. Unconscious twenty-six days. Recovery with residual left hemiplegia and personality changes.*

M. E., a schoolgirl, aged 16, was admitted to the hospital thirty minutes after an accident. There was a laceration on the dorsal surface of the right hand and a contusion in the left temporal region. On admission, the patient was said to have been severely shocked, pulseless and vomiting, and it was thought that the course would end fatally in a few hours. I first examined her nine hours after the accident, at which time she was unconscious and restless. The right arm and, to a less extent, the right leg were being moved constantly; the left arm and leg moved very little. The deep reflexes on both sides were present and not increased. There were very rapid pulse and respiratory rates, and the axillary temperature was almost 106 F., as shown by figure 13. The breathing was noisy, and coarse râles were heard throughout the chest. At the time of examination, the patient was lying in the dorsal position with the head flat. When turned on the right side with the head elevated, there was very free flow of cerebrospinal fluid from the nose. While she was in the dorsal position this fluid was evidently trickling into the trachea and was responsible for the râles and the noisy breathing, which immediately improved after the position was changed. A diagnostic lumbar puncture was done, a very small quantity of blood-stained cerebrospinal fluid under low pressure being withdrawn. Drainage of cerebrospinal fluid from the nose ceased after twenty-four hours. During the first four days the symptoms changed very little; the temperature, pulse and respiration ranges were lower, and the right arm and leg were moved only occasionally. At frequent intervals, there was jerking of the muscles of the right upper and lower extremities. Early on the fifth day, the patient was very restless; the axillary temperature rose to 104.6 F., and the general condition seemed less favorable. As the left temporal region had been injured and there had been evidence of irritation of the right arm and leg, a left subtemporal decompression was undertaken as a means of last resort. Under local anesthesia, a small opening was made. A loose film of blood was found over the cortex; there was diminution rather than increase of intracranial pressure, and the pulsations of the brain were feeble. The course was uninfluenced by the operation, the temperature registering 106 F. by axilla twenty hours afterward. As will be seen by figure 13, the temperature and pulse rate remained high, gradually returning to normal over a period of fifty-one days. Because of the state of unconsciousness and, after the first few days, the motionless condition of the patient, it was not until the third week that one could determine the exact state

of the motor difficulty. At this time, there was definite weakness of the left side of the body with increased reflexes and a positive Babinski sign and ankle clonus. The right leg and arm at this time were being moved in a more normal manner. Early in the course, there was dilatation of the left pupil and drooping of the left lid. As the patient regained consciousness, there was inability to move the left globe inward. The results of the fundus examination were unimportant except for pallor of the left disk. The mental state of the patient was unusually interesting, as she remained entirely unconscious, taking food and sometimes blinking the eyelids, but showing no other sign of consciousness until the twenty-sixth day after the accident, when she opened her mouth when asked to do so, and seemed to recognize her parents. Two days later, she seemed to know her mother, and from that time on, consciousness improved, and when discharged fifty-one days after the accident, she was fairly well oriented. Her mental condition has never been entirely normal, but there has been a gradual improvement since discharge from the hospital two and one half years ago. For many months after the accident, the patient was overtalkative, quarrelsome and explosive of temper. Memory of recent events was poor and judgment defective. She was unable to carry on her usual work at school. The motor disturbance of the right side of the body had entirely cleared up, but there was well marked spastic hemiplegia on the left. There was improvement in the extra-ocular muscles.

#### GROUP VII: HEMORRHAGES IN THE BRAIN STEM

The symptomatology of cases in this group is similar to that of group VI, and the grouping is made chiefly on the basis of the lesions studied post mortem. In the two following cases, the early course suggested the possibility of a group VI type of lesion. This possibility, however, was dismissed because of the spinal fluid pressure readings of 135 mm. of water in one case and 185 mm. in the other, the pressure readings in group VI being always very low.

CASE 18.—*Unconscious on admission. Deep coma the following day, continued throughout the course. Cerebrospinal fluid pressure readings normal. Death on the fifth day.*

W. I., a married man, aged 60, was admitted to the hospital in an unconscious condition one hour after an automobile accident. The blood pressure on admission was 95 systolic and 50 diastolic, the temperature 102 F., the pulse rate 99; the respirations, which were 28 per minute, were labored. There was bleeding from the right ear, fracture of the right ulna and lacerations of the face. The roentgenograms showed a small linear fracture in the right temporal region. On the following day, the blood pressure was 100 systolic and 70 diastolic and the temperature 104 F., the pulse and respiratory rates had increased; all indicating an unfavorable progress. A lumbar puncture at this time revealed slightly blood-stained cerebrospinal fluid under normal pressure. On the third day, there was evidence of consolidation in the bases of both lungs; the cerebrospinal fluid pressure was 130 mm. of water. On the fourth day, the cerebrospinal fluid pressure was 135 mm. of water; the patient was profoundly unconscious; the temperature was very high, and the respiration and pulse rates were still fast. The cerebral symptoms were now thought to be exaggerated by the pulmonary condition, which was increasing. Before death on the fifth day, the temperature rose to 106.5 F. and the respiratory rate to 48 per minute.

The labored breathing, profound unconsciousness, normal cerebrospinal fluid pressure and absence of spasticity were against placing this case under group VI. The small amount of blood in the cerebrospinal fluid did not indicate that the case belonged to group IV, as the early serious symptoms were out of proportion to the amount of blood. It was therefore concluded that the early serious symptoms were due to hemor-

Fig. 14 (case 18).—Illustrating group VII. Blocks through the anterior hind-brain segment.

rhage in the brain stem and operation was not advised. The pneumonia was considered partly responsible for the late symptoms. Sections of the brain stem are shown in figure 14 with extensive bleeding in the dorsolateral portion. In figure 15 blood is shown surrounding vessels at a point some distance from the large hemorrhage. Figure 16 shows a small vessel, a large amount of hemorrhage surrounding it and well advanced softening in the adjacent area.

Fig. 15 (case 18).—A section from the preceding figure showing blood outside the blood vessel.

Fig. 16 (case 18).—Photomicrograph of a section from figure 14 showing a small blood vessel with the extravasated blood in the surrounding tissue.

The second patient in this group had clear cerebrospinal fluid with a somewhat higher pressure reading, but the clinical course and lesions in the brain stem were similar to the first.

CASE 19.—*Drowsy and irrational on admission. Marked elevation of temperature. Clear cerebrospinal fluid. Death on third day.*

G. R., a schoolboy, aged 9 years, was admitted to the hospital following an injury to the right side of the body and the head when hit by a truck. On admission, he was conscious and complained of a severe pain in the right side of the head. The temperature was 101 F., the pulse rate 99 and the respirations 28 per minute. The following day he was drowsy and irrational, and his temperature rose to 104.4 F. On the third day the temperature was 106.5 F., the pulse rate 105 and the respirations 40 per minute. Lumbar puncture revealed clear cerebrospinal fluid with a pressure of 185 mm. of water. Following the puncture, the respirations were slow and the pulse rate very rapid. Death occurred two hours later, on the third day.

Until the lumbar puncture revealed clear cerebrospinal fluid with a high normal pressure, this case was thought to belong to group VI. After the puncture, the possibility of hemorrhage of the brain stem was considered. Unlike the preceding case, there were no macroscopic hemorrhages. Figure 17, a low power section of the brain stem near the fifth nucleus, shows a large amount of blood within the tissue. Figure 18 shows the presence of round cells in the perivascular space similar to the condition described by Osnato and Giliberti<sup>8</sup> and later by Cassasa.<sup>9</sup> Figure 19 shows a distorted vessel with extravasated blood in the center of an area of softening. This section was found in the corpus striatum on the left side.

Some patients with lesions of this sort evidently recover, so that care should be taken to carry out general treatment. Certainly nothing is accomplished by operative procedures.

#### SUMMARY OF SIGNS, SYMPTOMS AND TREATMENT IN THE SEVEN GROUPS

GROUP I: *Depressed Fractures.*—The symptoms vary from those of slight concussion to those of severe compression. The diagnosis is determined by inspection, palpation and roentgen examination of the skull and the neurologic disturbance indicating cortical injury. The treatment consists in early elevation of the bone fragments, inspection of the underlying dura and cortex and replacement of the fragments.

GROUP II: *Compound Fractures, With or Without Depression.*—Symptoms may range from slight evidence of concussion to serious

disturbance due to associated brain destruction and bleeding. The main object of treatment is the prevention of further destruction of cortex through pressure or infection and is accomplished by early cleansing of the wound.

GROUP III: *Extradural Hemorrhage*.—The signs and symptoms are those of increased intracranial pressure, usually appearing within the first few hours but sometimes in cases with small clots delayed for several days; focal disturbance, chiefly irritative, and later paralysis of the motor area associated with aphasia if the clot overlies the speech area. The treatment consists in early evacuation of the clot and control of the bleeding, usually accomplished through a subtemporal decompression opening.

GROUP IV: *Blood Overlying the Cortex*.—The symptoms in this group depend on whether the blood is distributed over a small area unmixed with cerebrospinal fluid and clotted or mixed with cerebrospinal fluid and distributed through the entire subarachnoid space. If present in the form of a clot, the symptoms are practically the same as in the preceding group, and the treatment consists in the removal of the clot as early as possible. If the blood is mixed with the cerebrospinal fluid the symptoms are due to irritation rather than to pressure, there is extreme restlessness and rapid pulse and respiratory rates. The headache is neuralgic. The onset of symptoms depends on the degree of richness of the blood in the cerebrospinal fluid. If the mixture is very rich, the symptoms appear early, while a small amount of blood in the cerebrospinal fluid may not produce symptoms until the end of the first week. The treatment consists in drainage of the cerebrospinal fluid, which if commenced early can frequently be accomplished through repeated lumbar punctures. Subtemporal decompression with drainage may be required early in cases of serious injury and in cases in which serious signs of pressure indicating cerebral edema develop several days after the injury.

GROUP V: *Cortical Injuries*.—(a) *Cortical Lacerations*: The symptoms in this group are usually severe because of the direct injury to the cortex and the likelihood of the escape of a large amount of blood. The symptoms depend on the portion of the cortex lacerated. The treatment consists in exposure, if possible, of the lacerated area, often requiring a bone flap. In many of these cases the laceration may not be located, and the treatment consists in the removal of the blood clot or bloody cerebrospinal fluid.

(b) *Diffuse Superficial Extravasations*: Diffuse superficial extravasations cause a serious general upset characterized particularly by delirium which may last for many weeks. These patients are generally operated on because of the serious early symptoms, the condition being

discovered in the course of the operation. The recognition of the condition is important from the standpoint of prognosis, as it indicates a slow, tedious course with mental upset terminating in recovery after many weeks.

(c) *Single or Multiple Cortical Clots:* Single or multiple clots produce symptoms of increased intracranial pressure and disturbance of function if in an active area. The treatment consists in exposing the area of cortex containing the clot so that it may be entirely removed as in the case of a tumor. This is not difficult in the case of single clots involving active cortex. Multiple cortical clots, if of any size, produce serious symptoms of increased intracranial pressure and may be associated with a large amount of blood overlying the cortex. Many of these cases end fatally no matter what method of treatment is employed.

*GROUP VI: Extravasations in the Vein of Galen System.*—This is an infrequent type of lesion characterized by rapid respiratory and pulse rates, hyperpyrexia, spastic musculature and abnormally low intracranial pressure with only a moderate disturbance of consciousness in the beginning. Operative treatment and therapeutic lumbar punctures avail little. The treatment, therefore, consists in general care of the patient in the hope of preventing such complications as pneumonia. Patients who survive show residual symptoms.

*GROUP VII: Hemorrhage in the Brain Stem.*—The symptoms in these patients are similar to those in the previous group, but the cerebrospinal fluid pressure is not abnormally low and there may be no blood in the fluid, while in the previous group there is generally some staining of the cerebrospinal fluid. In the absence of symptoms of pressure with clear cerebrospinal fluid there is obviously nothing to be gained in subjecting these patients to operation. If the lesions are small, recovery may take place, but with large hemorrhage or numerous scattered lesions, the patients usually die.

# THE DIFFERENCES BETWEEN HIGH AND LOW INTESTINAL OBSTRUCTION IN THE DOG

AN ANATOMIC AND PHYSIOLOGIC EXPLANATION \*

JOHN J. MORTON

The many different results obtained by investigators in experimental intestinal obstruction can be explained to some extent by the variations in the technic employed. Careful study demonstrates that there are three distinct pictures of disease included under the title intestinal obstruction. The obstructions high in the duodenum or at the pylorus result in dehydration, loss of chlorides from the blood and tissues, and alkalosis, but no real intoxication. The animals can be made to live for long periods by supplying water and sodium chloride; death is probably due to starvation. The second type is that of strangulation with resulting rapid necrosis and early profound toxemia. These animals die quickly from toxemia or peritonitis, often with little evidence of dehydration or dechlorination. The third group is characterized by high or low obstruction in the intestine, associated with dehydration, loss of chlorides, alkalosis and a toxemia. There is usually a latent period before the toxic symptoms are manifest but the intoxication is the dominant feature of the later stage of the process. It is little influenced, even though water and sodium chloride are supplied in sufficient amount.

The following observations relate especially to this last type of intestinal obstruction. Part of the experimental data has not been completed and will be reported later, but enough evidence is at hand to indicate the trend of the results. An attempt to review the literature will not be made as this has been excellently covered recently by Cooper.<sup>1</sup>

Certain differences have been consistently noted between obstructions made high and those made low in the small intestine of the dog. These differences result no matter how the obstruction is brought about, whether by simple ligature, division and inversion of the ends, or by closed loops with or without anastomosis to reestablish the continuity. It is generally conceded that the nearer the obstruction is to a point below the openings of the common and pancreatic ducts, the more severe the symptoms. As the obstruction occurs farther and farther

down the intestine, the onset of symptoms is slower and the toxemia less rapid. Roger<sup>2</sup> showed that dogs with obstruction in the duodenum lived on the average from twenty-four to forty-eight hours; with obstruction at the midintestine, they survived for five to six days, and if the terminal ileum was blocked, death came only after ten or twelve days. Hallion and Gayet<sup>3</sup> gave almost identical figures. Death followed obstructions in the duodenum in from twenty-four to seventy-two hours; dogs with upper jejunal obstructions lived from five to six days; those with obstructions in the terminal ileum survived for ten or twelve days; whereas rectal obstructions were compatible with life for as long as twenty-eight days. Many other writers could be quoted to support this observation. It is true for all of the species of laboratory animals so far tested. When a closed loop is made the same condition obtains, the high closed loops causing death more quickly than those lower in the intestinal tract. An additional fact of great interest is that the shorter the closed loop, the more intense and rapid the intoxication (Brooks, Schumacher and Wattenberg,<sup>4</sup> Dragstedt and others,<sup>5</sup> Copher and Brooks<sup>6</sup>).

These facts are used as evidence against the theory that bacteria play an important part in the production of the toxemia. It is well known that the normal upper small intestine is relatively sterile (Cushing and Livingood<sup>7</sup>), whereas the terminal ileum and large intestine swarm with bacteria. Why, therefore, if bacteria play any part should a high obstruction be more toxic than a low one, and why should a short closed loop be more toxic than a long one?

Recent observations tend to show that the upper intestinal tract is not completely sterile, especially under conditions of abnormal physiology. After partial obstruction there is a great increase in the bacterial flora in the duodenum (Meleney, Jobling and Berg<sup>8</sup>). Anything which

disturbs the chemical or motor functions of the stomach may lead to growth of micro-organisms in the upper intestinal tract (MacNeal and Chace,<sup>9</sup> Gorke<sup>10</sup>).

Attempts to eliminate bacteria from the intestinal tract for experimental purposes by the use of antiseptics result in little success. Practically all investigators agree that bacteria are present in enormous numbers in obstructed intestinal contents and in closed high loops. It is possible to demonstrate that this rapid growth occurs in loops of bowel which gave a negative culture before obstruction (Stabins and Kennedy<sup>11</sup>). Conversely, in some animals with long closed loops without evidence of toxic symptoms, my co-workers and I have been unable to get growth of bacteria on culture, although there was a large quantity of material in the loop. This material, extracted according to Whipple's method, was not toxic for dogs on intravenous injection. Davis and Stone<sup>12</sup> proved that secretions collected by washing through a loop of intestine were not toxic on intravenous injection unless allowed to incubate for a period of time. Dragstedt, Moorhead and Burcky<sup>13</sup> claimed that closed intestinal loops in which bacteria were removed were compatible with life even if the blood supply was completely occluded. Dragstedt, Dragstedt, McClintock and Chase<sup>14</sup> repeated this assertion, claiming that autolysis and reabsorption of the aseptic loop itself could take place without sufficient toxicity developing to kill the animal. Dragstedt and others,<sup>5</sup> in a more extensive series, came to the conclusion that it was impossible to sterilize even a short piece of intestine by chemical antiseptics, but that mechanical washing of a loop with ether was compatible with life in 50 per cent of the cases. This did not prevent formation of a toxin, but it did prevent absorption. Simple astringents, such as tannic acid, with no germicidal properties, were just as effective. The presence of bacteria in the lumen was necessary for the production of toxic substances and in their absence these substances did not form.

From the evidence at hand it is impossible at present to exclude bacteria from a rôle in the production of the toxemia.

Assuming that the bacteria produce toxins within the lumen of the intestine, it is still necessary for these toxins to be absorbed. All investigators agree that the toxins wherever formed are absorbed somehow to give the systemic toxemia. It is equally certain that the normal intestinal tract has a defensive mechanism against the absorption of toxins of high colloidal structure. This must necessarily be true for the handling of the many toxic split products of normal digestion.

One group of workers finds that normal secretions are nontoxic, whereas another group reports that all intestinal contents are toxic. It does not take much imagination to admit the possibility of the latter hypothesis if one considers the toxic substances formed in normal digestion. On the other hand, Whipple<sup>15</sup> and his followers have clearly demonstrated that a toxemia can arise from an occluded loop of intestine from which gastric juice, bile, pancreatic secretion and food have been excluded. It seems probable, nevertheless, that under certain conditions even the normal contents of the intestine may be toxic if tested by intravenous injection.

Repeated attempts have been made to cause toxemia by the introduction of obstructed loop fluid into experimentally obstructed intestine. There is no evidence that the toxemia has in any way been hastened when such measures are used (Cooper<sup>1</sup>).

Large amounts of *B. welchii* toxin (from 10 to 20 cc.) were introduced into closed loops of intestine by Stabins and Morton<sup>16</sup> with no more rapid toxemia, as measured by blood studies and clinical evidence, than in the control group. This toxin could not be made to pass the defensive barrier more quickly when mixed with a phosphate buffer solution of  $p_H$  8, or with bile aspirated from the animal's own gall-bladder. Colloidal dyes of large molecular structure, brilliant vital red and trypan blue, and those of smaller molecular weight, congo red, cloth red and congo blue, were placed in obstructed loops but could not be demonstrated in the vessels or in the wall of the living intestine on immediate frozen section. Colloidal silver 2 per cent, which is selectively absorbed by the lymphatics, was likewise used unsuccessfully. When a patch of gangrenous bowel was perforated, however, this silver could easily be traced as a brown stain up the lymphatics of the anterior mediastinum to the anterior mediastinal lymph nodes. Great care was always taken in introducing these substances that there was no leakage into the peritoneum. The punctures for introducing the solutions into the obstructed loops were made in the bowel adjacent to the loop and

the second occluding tape tied afterward so that no damage was done to the wall or mucosa of the obstructed segment.

Kagan<sup>17</sup> was unable to show that trypan blue could pass the living mucosa of the intestines of mice under various conditions of experiment. He did get a slight coloring on tops of the villi, in the goblet cells and in Paneth's cell granules but never in the histiocytes or reticulo-endothelium. Consequently, he concluded that this was a postmortem change. Necrotic tissue could be made to stain with this dye as he noted it in the kidney after sublimate poisoning.

Churchman,<sup>18</sup> however, did succeed in making gentian violet pass from the lumen of the bowel occluded between two ligatures through the whole wall to the outside. Gauze lying on the peritoneal surface was stained by the dye. This dye is of fairly high molecular weight, varying from 400 to 420, depending on the exact dye used.

It may be that small quantities of materials of colloidal structure do occasionally pass the barrier but the movement along the intestinal tract prevents an overwhelming toxic absorption, and detoxication takes place.

Most of the known poisons of complex colloidal structure, such as snake venom, ricin and abrin, and various bacterial toxins are entirely harmless when taken by mouth. These toxins are destroyed by the action of peptic or tryptic digestion and converted into simpler compounds. *Botulinum* toxin seems to be one exception to this rule, thus differing from the Klebs-Löffler toxin and the tetanus toxin. The *botulinum* toxin is regarded as an albuminous substance, consequently of a large molecular structure, and it passes through the intestinal tract of man into the circulation. It can be demonstrated in the blood of monkeys after oral administration (Dack and Wood<sup>19</sup>), and also is occasionally found in the blood of guinea-pigs under similar circumstances but not in the blood of rats (Dack<sup>20</sup>). Apparently most of the absorption occurs in the acid portions of the stomach and upper duodenum, and the toxin cannot be demonstrated in the tissues of intoxicated animals (Dickson<sup>21</sup>). Some species seem resistant to the passage of this toxin, the duodenum and ileum of rabbits being practically impermeable (Dack and Wood<sup>22</sup>). The lethal dose by mouth in mice

is 0.04 cc. compared to the subcutaneous lethal dose of 0.000025 cc. (Lippmann<sup>23</sup>). These facts show that the intestinal tract has a good defensive barrier in some species, so that many times the lethal dose can be handled. But a known poison of a highly complex nature can pass through the intestinal wall into the circulation in some species of animals and man.

Another bacterial toxin can be made to pass the intestine at times as shown by Detrich.<sup>24</sup> Mice which can withstand huge doses of tetanus toxin by the gastro-intestinal tract under ordinary conditions were killed by it if bile or bile salts were fed previously.

Evidence has been slowly accumulating which proves that the intestine is not so completely impermeable to colloidal sized particles as was previously believed. Schloss and Anderson<sup>25</sup> demonstrated that the intestinal tract of infants under certain conditions was slightly permeable to altered or unaltered protein. The presence of reaction bodies to cow's milk in the blood of the children was clearly indicated both by positive precipitin reactions to cow's milk protein, and by the fact that guinea-pigs could be passively sensitized to cow's milk by blood from these children. The precipitin reaction was positive in eighty of ninety-eight infants tested. The precipitin was not present in the blood at all times. Anderson, Schloss and Myers<sup>26</sup> found later that egg white, sheep serum and almond meal all gave precipitin reactions in the blood of normal children.

Hektoen, Kanai and Dragstedt<sup>27</sup> fed fresh thyroglobulin (beef thyroids) to dogs and got positive precipitin reactions for it in the dog's blood. The beef thyroglobulin was present in the portal serum, the systemic serum and occasionally also in the urine. The greater concentration in the portal serum and the apparent absence from extracts of digestive mucosa point to its direct absorption into the tributaries of the portal system. Hettwer and Kriz<sup>28</sup> sensitized guinea-pigs to horse

serum. Anaphylactic reactions could be produced by introducing horse serum into a ligated loop of the small intestine. Under conditions of increased intra-intestinal pressure, proteins were not only absorbed but a certain portion actually reached the blood stream in undigested form. This portion was large enough and the absorption rapid enough for sensitization of a normal animal or for intoxication of a previously sensitized animal. In a further study<sup>29</sup> they determined that anaphylaxis could be produced by injection of large amounts of horse serum into unligated intestine. They also found that the presence or absence of digestive juices made no difference. Short closed loops were more effective in producing symptoms than long loops. There was a definite relationship between the length of loop and the amount of serum necessary to produce anaphylaxis. A noneffective dose in a closed loop could be made effective by increasing the intra-enteric pressure, or by shortening the loop in which it was contained.

Kendall and Varney<sup>30</sup> induced an anaphylactic reaction in strips of intestine of the guinea-pig sensitized to egg albumin or horse serum by application of the homologous antigen to the mucosa. This indicated a passage of the whole protein through the intestinal wall. Walzer<sup>31</sup> found that he could passively and locally sensitize the skin of almost every person to a particular food by intradermal injection of serum from a hypersensitive patient. Subsequent ingestion of the food under proper circumstances resulted in the formation of a wheal at the sensitized site. He concluded from a study of over 200 persons that in most of them a detectable amount of certain types of protein frequently enters the blood stream in an unaltered state by way of the digestive tract. Later investigations<sup>32</sup> showed that egg or fish proteins could be detected by this local reaction in 85.3 and 93.8 per cent respectively of those tested.

MacCallum<sup>33</sup> claimed that intact egg protein was absorbed directly through the cells of the villi into the lacteals in guinea-pigs and rabbits.

It seems fair to assume from the evidence here presented that small amounts of protein may pass through the wall of the normal intestine.

There are many poisons formed in the intestine, some of which are of relatively simple structure. Histamine may be taken as an example. Its presence has been shown in the human cecum and transverse colon (Meakins and Harrington<sup>34</sup>). Gerard<sup>35</sup> found this substance in isolated closed loops of large or small intestine. A fair average sample was from 2 to 3 mg. per hundred cubic centimeters of the fluid. He also noted a combined histamine derivative. Sterile jejunal fluid did not contain histamine but it was present in the mucosa of normal and of closed loops of jejunum. Meakins and Harrington<sup>36</sup> observed that the absorption of histamine as measured by the rate of fall in blood pressure was greatest from the ileum, somewhat less from the duodenum, and much less, though still perfectly definite, from the cecum and stomach. The liver exerted a protective function which was probably more mechanical than chemical. When the mucous membrane was damaged by cutting off the blood supply for from five to fifteen minutes, the absorption took place at first with a rush and then almost ceased. Although Ingvaldsen, Whipple and others<sup>37</sup> admitted that a small amount of histamine was present in the content of obstructed bowel, they believed it insufficient to contribute to its toxic nature. Koessler and Hanke<sup>38</sup> fed dogs and guinea-pigs a known amount of histamine dichloride and examined the intestinal contents, intestinal walls and the liver for it. The animals were killed after a certain period of time. The histamine passed into the intestinal wall as such, for it was found there; it was also found in the liver. Over half of the amine was absorbed within two hours, and yet enormous quantities of histamine could be introduced into the stomachs of the animals without eliciting a marked systemic reaction. A small fraction of the histamine appeared in the intestinal wall and a small amount in the liver. If all the histamine that disappeared from the alimentary tract were cast into the general circulation it would certainly have led to a marked reaction. It was shown that the liver capillaries were no more effective than the capillaries of the lower extremity in protecting an animal against intoxi-

cation from histamine. In the studies of the intestinal tract, therefore, the capillary network must act as a buffer. The histamine was perhaps rendered pharmacologically inert in its passage through the wall of the intestine. Hashimoto<sup>39</sup> demonstrated that the nonprotein nitrogen of the plasma could be raised from 50 to 94 per cent above the normal by acute histamine poisoning in dogs. He was unable to produce the complete picture of the toxemia of intestinal obstruction but believed he could partly do it.

Wangensteen and Loucks<sup>40</sup> placed histamine in normal and obstructed small intestine with and without strangulation. Although there was a great fall in arterial blood pressure following the release of a strangulating mechanism, they thought this was due to a substance liberated by the autolysis of the intestinal mucosa. They concluded that the absorption of histamine from the lumen of a strangulated segment that was still viable did not appear to be great.

Williams<sup>41</sup> worked on the hypothesis that *Bacillus welchii* toxin was partly responsible for the toxemia in intestinal obstruction. He based his assumption on the similarity in the clinical picture to that of gas gangrene. He gave evidence of the proliferation of *B. welchii* in the small intestine in obstruction. He found the toxin present in the small intestine under similar conditions but not in the normal small or large intestine. He materially reduced the case mortality in human intestinal obstruction and peritonitis by the therapeutic use of *B. welchii* antitoxin.

Clinical confirmation of this important work has been delayed owing to the difficulty in obtaining *B. welchii* antitoxin. Morton and Stabins,<sup>42</sup> however, showed experimentally in dogs that there was a protective action of *B. welchii* antitoxin when combined with surgical procedures. The antitoxin seemed to be specific in its action. Stabins and Kennedy<sup>43</sup> demonstrated the almost constant presence of *B. welchii* in the loops of bowel above the obstruction. Kendall and Schmitt<sup>43</sup> isolated a histamine-like growth product from cultures of the gas bacillus. Kendall and

Varney<sup>44</sup> were able to produce slow but progressive contractions of the intestinal muscles on application of histamine and this histamine-like product of the Welch bacillus to the mucosa. This pointed to a definite but slow absorption from the lumen of the intestine through the mucosa. Ordinarily these substances would be taken away through the blood stream as fast as they were absorbed. The addition of a weak alkali accentuated both the rate and height of the contractions. Scholefield<sup>45</sup> claimed that a neutral or a slightly alkaline medium was necessary for the best growth of *B. welchii*. Habler<sup>46</sup> exhibited by chemical studies a factor which worked for blood alkalosis.

There has been much speculation and experiment as to the pathway of absorption of the toxin from an obstructed intestine. Attempts to isolate the toxin from the blood have resisted all efforts except in animals almost in the throes of death. Under such circumstances, Sugito<sup>47</sup> and Scholefield<sup>45</sup> have found blood from the portal vein toxic for mice. Most investigators agree that the blood of animals with obstruction is harmless on injection into other animals. Absorption by the lymphatics has been postulated by another group of investigators. Costain<sup>48</sup> believed that he had demonstrated the toxins by the collection of lymph from the thoracic duct. Schulze<sup>49</sup> showed a hemorrhagic infarction of the mesenteric lymph channels and more or less outspoken blood thromboses in strangulation obstruction. The preparations revealed beautifully both the lymphatic and vascular channels. Murphy and Brooks<sup>50</sup> collected toxic blood-tinged material from a fistula of the thoracic duct when the intra-intestinal pressure was increased in a closed intestinal

loop. Chenut<sup>51</sup> concluded that the blood was not toxic in experimental occlusion but that the lymph was toxic at times. He thought that the toxins were in the main absorbed by the peritoneum and not by vascular or lymphatic channels. He showed experimentally that absorption was practically nil when the obstructed loops were put in an extraperitoneal position. He called attention to the great friability of the mucosa of the obstructed intestine. There was never death, in his opinion, without alteration in the intestinal wall, manifested first as gangrene on the tips of the villi. The poisons worked directly through these areas and through the wall to the peritoneum where they were absorbed.

Läwen<sup>52</sup> obtained a marked fall in blood pressure with little or no tendency toward recovery to normal when he "stripped" an intestine after ileus of twenty-four hours' duration. A proportion of his animals died. He conjectured that a poison which had gathered in the intestinal wall was thus forced quickly into the blood stream and caused central poisoning.

Schönbauer and Löffler<sup>53</sup> also claimed that the toxins and the tryptic ferments responsible for them could be demonstrated in the peritoneal exudates but Traum<sup>54</sup> was unable to confirm their work.

Many workers have insisted that pathologic changes must take place in the intestine before toxemia can occur (Brooks,<sup>55</sup> Eisberg,<sup>56</sup> Gatch,<sup>57</sup> Costain,<sup>48</sup> etc.).

The importance of increased intra-intestinal pressure has been stressed by van Zwalenburg,<sup>58</sup> Brooks,<sup>4</sup> Stone and Firor,<sup>59</sup> Braeye,<sup>60</sup>

Gatch<sup>61</sup> and others. Van Zwalenburg<sup>58</sup> placed an electric light in the lumen of the intestine and studied the effects of distention on the blood vessels. At 30 mm. of mercury pressure, some of the capillary streams were arrested; at 60 mm., some of the small veins were arrested and the current slowed in most of them; at 90 mm., all blood streams were moving slowly, many not at all and some in reverse, and at 130 mm., all circulation ceased. If the pressure was kept at from 80 to 90 mm. for one hour, the intestine was enormously congested. These important observations were disregarded for a long time although it seems likely that they have the greatest practical bearing on the problem.

Brooks<sup>55</sup> and his co-workers said that the shorter loops were more toxic because of the distention pressure.

Stone and Firor<sup>59</sup> indicated that whereas the normal intestinal mucosa was permeable to water, salts, certain carbohydrates and the split products of the digestion of fats and protein, in obstruction toxic substances accumulated in greater quantity and concentration under greater pressure for longer periods than the normal. They argued that these conditions might modify the permeability.

Braeye<sup>60</sup> concluded from further study that the mounting pressure within the bowel was an important factor in the absorption of the toxins. This pressure, however, delayed the circulation and slowed the dissemination of the poisonous material. A latent period of from ten to twenty hours was necessary before sufficient fluid accumulated in the bowel to increase the intra-intestinal pressure. The toxic properties, as a rule, required more than thirty-six hours to develop.

Gatch and others<sup>61</sup> repeated van Zwalenburg's<sup>58</sup> observations and confirmed them. They cannulated the mesenteric veins returning from a closed loop and measured the minute volume flow under experimental intra-intestinal pressure. When the gas pressure exceeded the blood pressure of the animal, there was still a residual blood flow from the mesenteric veins although all the vessels of the bowel wall were occluded. This was possible because of anastomoses through the vessels in the mesentery. The antimesenteric border of the bowel wall was entirely blanched when the gas pressure was equal to the blood pressure. On release of the gas pressure, the blood flow through the bowel wall was at times greater than normal.

Although there is conflicting evidence pointing toward the origin of the toxin and its pathway of absorption, it seems to me that the differences in toxicity in high and low intestinal obstruction in the dog can be explained on an anatomic and physiologic basis.

Experiments limited to two regions—the lower duodenum beyond the pancreatic and bile ducts, and the terminal ileum—were undertaken to test this theory. Equally measured segments of these regions were compared in dogs by Morton and Sullivan.<sup>62</sup> Ether anesthesia was used throughout. The blood supply was injected through the thoracic aorta with Hill's barium mixture and roentgen exposures were made of segments of the duodenum and ileum (fig. 1). Segments were also run through alcohol and cleared in oil of wintergreen according to Spalteholtz's technic (fig. 2). This gave a comparison of the arteries and larger vessels in the loops. Other animals were given similar injections with india ink in order to obtain a picture of the capillaries. The blood supply of obstructed, closed, equal-sized loops of duodenum and ileum was likewise injected with india ink (figs. 3, 4 and 5). The gross appearance of the cleared, barium injected bowel showed

Fig 1—In this figure is shown 1, the barium injected vessels of the ileum of the dog; 2, the barium injected vessels of the duodenum of the dog

a more rich supply of arteries in the duodenum than in the ileum. The roentgen exposures confirmed this. There was also a much richer capillary network in the duodenal villi and a wider more extensive anastomosis all through the duodenal wall. The duodenal villi appeared more plump and closer together than the long, slender graceful villi of the ileum. Under conditions of closed loop obstruction the duodenal villi were flattened out so that the capillary loops formed a dense dilated mat with overdilatation of the vessels immediately below the mucosa. The ileum under similar circumstances showed less effective "ironing" down of the villi and less submucosal engorgement.

<sup>62</sup> Morton, J. J., and Sullivan, W. C: A Comparison of the Anatomic and Physiologic Differences Between Simultaneous Equal-Sized Closed Obstructions of the Duodenum and Ileum, in press.

In all the animals studied, the duodenum was much larger in caliber than the ileum. The duodenum also appeared to be more capable of withstanding strain and pressure. The walls were thicker and the musculature more pronounced. The surface area of the mucosa measured without regard to the foldings of the villi averaged a little more than a ratio of 3:2 in favor of the duodenum.

The secretion rates of the duodenum and ileum were compared. Two methods were employed. In the first experiments a loop was isolated

Fig. 2.—Drawings from antimesenteric border of specimens of the duodenum and ileum of the dog. The blood supply was injected with a barium mixture and the intestine cleared according to Spalteholz's technic. The arteries and arterioles are much more numerous in the duodenum.

by placing a tape across the lumen, and dividing the bowel 10 cm. below the tie. The proximal end was then closed around the tube which drained into a rubber bag attached outside the body wall. The distal loop was turned in and a side to side anastomosis made above the tape tie. In this way segments of duodenum and ileum 10 cm. in length with intact mesenteries were connected with rubber balloons outside the

Fig. 3.—In 1 is shown the blood supply of the dog's duodenum injected with india ink and cleared. The richness of the capillary bed is well shown, especially in the villi. In 2 is shown the effect of increased intra-intestinal pressure on the duodenum in an obstructed loop. The villi are compressed and the submucosal vessels are distended. The capillary loops show intact walls;  $\times 50$ .

Fig. 4.—In 1 is shown the blood supply of the dog's ileum injected with india ink and cleared. The villi are long and slender. The blood supply is not so rich as in the duodenum. In 2 is shown the effect of obstruction. There is flattening down of the villi, but the effect is not so marked as in the duodenum when obstructed for the same length of time;  $\times 50$ .

body and the continuity of the intestine reestablished above these loops. The duodenum secreted from five to ten times more fluid than the ileum in the same period of time. This was a fairly constant observation in experiments of this type. Occasionally, the tubes became clogged with a thick mucous-like secretion so that the measurements could not be recorded. It was considered more accurate to make simultaneous equal closed loops of duodenum and ileum and to measure the amount of fluid

Fig. 5.—In this figure is shown: 1, normal ileum with its blood supply injected with india ink and cleared, low power photomicrograph; 2, the same showing the effects of obstruction;  $\times 12$ .

excreted into each under these conditions. The continuity of the intestine was interrupted in these instances by two tapes tied across a 10 cm. segment of duodenum, and by a similar arrangement in the ileum. Every twenty-four hours the animals were anesthetized, the contents of the closed loops aspirated, measured and returned to their respective segments. A report of one experiment which was typical for others of

the same type will be given. At the end of twenty-four hours the duodenal loop contained 5 cc. of fluid, whereas the ileum had only 0.5 cc.; at the end of forty-eight hours, there was 10 cc. of fluid in the duodenum and 1 cc. in the ileum; and at seventy-two hours, the duodenum held 30 cc. and the ileum only 2 cc. The difference between the distended, bluish, engorged duodenal loop and the flabby, apparently normal ileal loop was striking.

It was apparent from these observations that the secretion rate in the duodenum was much greater than in the ileum.

The intra-enteric pressure was recorded by a water manometer in a few experiments and confirmed the observations of Owings, McIntosh, Stone and Weinberg.<sup>63</sup> These investigators noted that the normal intra-intestinal pressure varied between 2 and 4 cm. of water. There was only a slight rise in this pressure for the first twenty-four hours following operation. During the second twenty-four hours of obstruction the sustained pressure remained between 6 and 8 cm. of water, while the degree of pressure reached at the maximum of peristalsis rose considerably. In dogs with high obstruction this pressure varied from 30 to 45 cm., while it generally took until the third day for the pressure in the dogs with low obstruction to reach this same level. Periods of violent peristalsis came on earlier and were more frequent in animals with high obstruction than in those with low obstruction. The pressure in isolated loops reached a higher degree (70 cm. of water) than that in dogs with simple intestinal obstruction. In our animals with simultaneous closed duodenal and ileal loops of equal length, the pressures were recorded and indicated a marked increased tension in the high loops. A typical example gave the normal pressure for a ligated closed loop of duodenum, immediately after closure of the abdominal wall, as 5.5 cm. of water; for a similar closed loop of ileum, it was 5 cm. of water. At the end of twenty-four hours, the pressure in the duodenal loop recorded between 28 and 36 cm. of water depending on peristaltic conditions, whereas the ileal loop still measured only 4.5 to 5 cm. of water pressure. After forty-eight hours, although a leakage had occurred alongside the stem of the duodenal cannula, the pressure within the loop still ranged from 12 to 18 cm. of water. The ileum at this time still showed only from 5 to 6 cm. of pressure. The animal was then killed to verify the condition of the two regions.

The bursting pressures of equal segments of duodenum and ileum were compared according to the method devised by Cutting,<sup>64</sup> with the exception that compressed air was used instead of the pump. His

64. Cutting, R. A.: The Relative Mechanical Strength of Enterostomies Performed With and Without Clamps, *Arch. Surg.* **17**:658 (Oct.) 1928.

observations on the strength of the intestine were confirmed. There was a moderate variation in the results obtained, but in general the amount of force necessary to cause rupture of the segment was approximately the same. Both duodenum and ileum usually resisted air pressure of well over 500 mm. of mercury. Rupture most often took place on the antimesenteric border near the ligature. By variation in the tie, more pressure could be sustained, but there was too little differences between the duodenum and ileum to be significant.

Both the duodenum and ileum could stretch considerably in length and circumference. The ileum could perhaps lengthen and distend slightly more than the duodenum. It seemed from a limited set of experiments that the ileum could double in width and lengthen almost half its original length before rupture, whereas the duodenum could increase only about two thirds of its original width and could lengthen only one third of its original length.

It seems probable that the reasons for the greater toxicity of high obstructions over low obstructions lies in the anatomic and physiologic differences between these two areas of bowel. The high obstructions also represent a short loop instead of the whole length of the small intestine. This shorter segment has everything in its favor for a more rapid absorption and toxemia. The secretory rate is much more pronounced and the increase in intra-enteric pressure much more rapid, whereas the distensibility is perhaps slightly less than for low bowel. This is true even if the bile, pancreatic and gastric juice be excluded from the picture, but there is every reason to believe that the pressure and toxicity would be greater if they functioned.

From this study of the anatomy and physiology and from evidence already published in the literature, it is possible to picture a theoretical sequence of events in the development of the toxicity in intestinal obstruction.

There is first a latent period of varying duration during which no symptoms are manifest. In this time, fluid is being secreted into the loop and bacterial growth is taking place.

Histamine or histamine-like bodies are formed and taken up into the intestinal wall.<sup>65</sup> The capillaries become distended and the circulation slowed. The bowel at this stage shows "the dusky flush of capillary congestion and a network of venules filled with dark blood" so aptly described by Dale.<sup>66</sup>

There is a loss of fluid from the capillaries into the tissue spaces giving the soggy edematous bowel found at this time. This fits well

65. Gerard (footnote 35). Meakins and Harrington (footnote 36). Koessler and Hanke (footnote 38).

66. Dale, H. H.: Capillary Poisons and Shock, *Bull. Johns Hopkins Hosp.* 31:257, 1920.

with Dale's<sup>67</sup> description that "within a few minutes of the injection of histamine as much as one half the plasma may have passed from the vessels, probably leaving many of the capillaries clogged with a viscid corpuscular cream. . . . A large number of bacterial products exhibit this type of action, including both soluble products and substances liberated only by lysis of the bacteria."

Alteration in the capillary tone leads to stasis and lack of oxygen. Landis<sup>68</sup> has shown how effective this oxygen lack is in causing a marked increase in permeability of the capillary bed. Tremendous osmotic pressure is thus developed toward the capillary loops. The intra-intestinal gaseous and fluid pressure also increases greatly.

Whatever toxins are present in the lumen or mucosa cells may be forced thus into the intestinal wall by some route—blood vessels, lymphatics, directly through cells or intercellular spaces—the exact mechanism being still an open question. Fisher and Moore<sup>69</sup> have shown that by changes in the blood salts, the cells of the intestinal mucosa can be altered so as to become permeable to substances to which they were once impermeable. The influence of increased hydrostatic pressure is shown by the fact that the amount of absorption by the blood vessels of the peritoneum as measured by salt solution can be more than doubled if large amounts are introduced into the peritoneum under pressure (Bolton<sup>70</sup>).

The toxins remain in the wall which has a circulatory and lymphatic stasis so that they cannot be removed. They are retained as in a sponge.

Increasing intra-intestinal pressure eventually squeezes the toxins out into the systemic circulation.

Necrosis is probably not necessary but may accelerate the process by exposing the capillary loops to direct action of the poisons. There is no doubt that large colloidal poisons will pass the capillaries in the peritoneum for instance (Bolton<sup>70</sup>), and once the epithelial barrier is down the same probably holds for the intestine. The injections with india ink show that the capillary loops remain intact even under considerable intra-intestinal pressure in closed loop obstructions. On the other hand, it is more than likely that the absorption rate is less the more the damage to the mucosa. It would be strange if the defensive reaction of the body were to fall down and not wall off absorption from a necrotic area by

thrombosis. When necrosis goes all the way through the wall, however, absorption becomes possible from the peritoneal side and rupture of the loop with rapidly fatal peritonitis gives another angle to the picture.

The course as outlined would explain the rapid toxemia following release of an obstructed strangulated segment. It is well established that the toxins formed in the occluded bowel are not absorbed by the normal intestine below. The reestablishment of blood and lymphatic circulation usually with hyperemia would rapidly wash out the retained toxins. It would also account for the bad results from much handling of the soggy obstructed bowel, and would explain the fatalities from the equally bad practice of stripping the loops of their contents.<sup>52</sup> It would indicate why the use of physostigmine (eserine) or other violent acting peristaltic drugs should be avoided. Even after a long period of obstruction, the bowel musculature appears to retain its irritability to stimuli of this kind (Frey,<sup>71</sup> McIntosh and Owings<sup>72</sup>). It would explain the more rapid course in obstruction after injection of pilocarpine due to the more rapid fluid secretion pressure (Roger<sup>2</sup>).

#### CONCLUSIONS

High intestinal obstruction is more toxic than low intestinal obstruction, because of anatomic and physiologic differences, as shown by tests in the duodenum and ileum of the dog.

These consist in a greater capillary bed in the duodenum which may take up and retain larger amounts of poison than a similar ileal loop.

There is a much greater fluid secretion rate in the duodenum than in the ileum.

This leads to a higher intra-enteric pressure.

The possibility of pressure necrosis and perforation is greater in the duodenum than in the ileum.

The increased intra-enteric pressure squeezes out the retained toxins into the general circulation faster than the body can detoxify them.

The bursting pressures of equal sized segments of duodenum and ileum are practically equal.

In simultaneous, equal, closed loop obstructions of duodenum and ileum in which a lethal outcome is allowed to take place if perforation occurs, the perforation is always in the duodenum and not in the ileum.

This is an index of the greater secretory hydrostatic pressure developed in the high segments.

The exact pathway of absorption of the toxins still remains a question.

## EXPERIENCES WITH CORDOTOMY\*

GILBERT HORRAX

The term cordotomy, as applied to the operation of that name, although theoretically meaning an incision anywhere into the spinal cord, is now generally considered to refer to an incision which divides the anterolateral fiber tracts. This procedure was devised by Spiller, in 1912, to relieve intractable pain in the legs or lower part of the body, and in the same year the operation was performed for the first time by Martin.<sup>1</sup> In 1920, and again in 1923, Frazier<sup>2</sup> reported two different series of cases in which he had performed the operation. In each series the results were largely successful. Reports by other surgeons have appeared since those of Spiller and Martin and of Frazier, notably the ones of Leighton<sup>3</sup> in 1921; of Peet<sup>4</sup> in 1926, and of Foerster<sup>5</sup> in 1927. Also, in 1927, a complete review of the subject with the report of a large series of cases was published in monograph form by Banzet.<sup>6</sup> The general tone of all these articles is highly optimistic, since in the majority of instances the operation accomplished the desired result.

To review briefly the physiology concerned in the situation, it may be said that the sensations of pain and temperature are carried up in the cord in the anterolateral columns on either side. Fibers carrying these sensations enter the cord through the various posterior roots, and after ascending from three to five segments in the gray matter of the same side, cross to the opposite anterolateral column, thence continuing upward until they reach their end-stations in the brain.<sup>7</sup>

5. Foerster: *Arch. f. Psychiat.* **81**:7 (Sept.) 1927.

6. Banzet: *La cordotomie*, Paris, 1927, Librairie Louis Arnette.

7. Foerster (Die Leitungsbahnen des Schmerzgefühls und die chirurgische Behandlung der Schmerzzustände, Berlin, Urban and Schwartzberg, 1927), according to a review in the *Brit. J. Surg.* **16**:172 (July) 1928, states that the pain fibers require only one segment to reach their position. This statement seems to be borne out in some of the cases here reported.

If pain is, and is expected to be, entirely unilateral, only the contralateral anterolateral tract need be sectioned; whereas if pain is present on both sides, both tracts must be incised. Since fibers entering the cord do not cross until they have ascended several segments in the gray matter of the same side, the operation must be performed at a level at least five segments above the segment level of the pain.<sup>7</sup> The highest level theoretically at which section of the anterolateral column could be made safely in order to avoid a possible phrenic complication would be at the sixth cervical segment. The operation, therefore, is limited on these grounds to patients having pain at or below the third dorsal segment, i.e., for pain in the trunk, pelvis and legs. The vast majority of patients, however, for whom cordotomy is indicated have pain in the legs or pelvis, and for pain in these situations the most convenient level surgically for a laminectomy may be chosen, namely, the middorsal region. Some of the more frequent conditions for which cordotomy may be indicated are: inoperable or metastatic carcinoma of the pelvic or abdominal organs; metastatic carcinoma of the spine; post-traumatic root pain from gunshot wounds or fractures of the spine; gastric crises and other pains due to tabes, either abdominal or in the lower extremities; postmyelitic root pains, and inoperable tumors of the spinal cord.

The technic of the procedure has been described carefully in the articles by Frazier, Peet, and Banzet, therefore, the details will not be repeated here. Suffice to say that a laminectomy of three vertebrae over the desired site gives ample room for the cord incision. After opening the dura and arachnoid, the dentate ligament on one side is grasped and the cord gently rotated sufficiently to give access to its anterolateral surface. The tract may then be sectioned either by including it in the curved needle designed by Frazier and cutting through the fibers thus held, or a straight, narrow knife may be inserted directly inward to a depth from 3 to 3.5 mm. at the pial reflection of the dentate ligament, and the section made by bringing the blade out to the surface at the level of emergence of a motor root, thus incising the anterolateral quadrant of cord in which the pain fibers are situated (fig. 1). The same procedure is carried out on the opposite side if a bilateral cordotomy is desired, the section being made at a slightly higher or lower level as convenient. By keeping anterior to the insertion of the dentate ligament, the pyramidal tract is avoided (fig. 2). If a posterior root is in the way it may be sacrificed, and the same is true of a motor root throughout the dorsal region. Little or no bleeding, at most a drop or two, follows the cord incision. The operation ordinarily may be performed under procaine hydrochloride anesthesia, although in some patients a few moments of gas-oxygen inhalation may be desirable when the intrathecal procedures are about to be carried out.

Fig. 1—Incision of anterolateral column after rotating cord by traction on the dentate ligament (from Peet Arch. Surg 13:156 [Aug] 1926)

Fig 2—Segment of cord incised, avoiding pyramidal tract which lies posterior to insertion of dentate ligament. The area incised should probably extend even further medially (modified from Peet. Arch. Surg 13:156 [Aug] 1926).

It is only by the gradual accumulation and report of individual experiences, together with a record, so far as possible, of the end-results, that the indications for, and the efficiency of, any operation may be judged. It is with these facts in mind that the present series of eight cases is recorded. The reports are in chronological order dating from August, 1923.

The first case is, in many respects, the most interesting one in the series. Representing as it did my initial experience with the operation, some of the good features and some of the difficulties are illustrated.

#### REPORT OF CASES

*CASE 1.—History.*—P. M., a woman, aged 52, referred by Dr. G. F. Dow of Reading, Mass., was first admitted to the hospital on Aug. 1, 1923, with the complaint of pain in the left hip and down the left leg. Three sisters and one daughter of the patient were said to be "bleeders." Twenty-four years ago she had had infected glands excised from her right axilla, and in the same year she had fractured her coccyx which was removed shortly afterward. She began having pain in the left hip and down the left leg in 1919. The pain was not relieved by local measures nor by osteopathic manipulations during the next year. In 1921, a uterine fibroid was removed without influencing her pain. From August, 1921, until November, 1922, she was under the care of a competent orthopedic surgeon, and during this time she spent eight weeks in a plaster cast, still with no relief from pain. She then went home and was confined to bed until she entered the Brigham Hospital on the medical service in May, 1923.

*Physical Examination.*—Aside from some secondary anemia, the only positive observation was hypertrophic arthritis of the lumbar spine shown by roentgen examination. Neurologic studies including lumbar puncture revealed no evidence of a tumor of the cord, and she was transferred to the surgical service for the relief of her pain with the diagnosis of "sciatica; chronic hypertrophic arthritis of the spine." She was having morphine daily.

As a precautionary measure, in order to get some idea as to whether a spinal section would relieve her pain, she was given spinal anesthesia with procaine hydrochloride on Aug. 21, 1923. This relieved her completely for several hours, so the operation seemed indicated.

*Operation.*—Aug. 27, 1923: Right cordotomy was performed. The spines and laminae of the seventh and eighth dorsal vertebrae were removed and the right anterolateral tract of the cord was incised at the level of the seventh dorsal spine. The fibers were included within the hook designed by Frazier, and cut through with his special curved knife. After this procedure a bougie was passed down between dura and arachnoid to the end of the spinal canal. As no obstruction was met, it was assumed that tumor was finally ruled out.

August 28: The patient was free from pain. Examination showed complete loss of pain sense over the whole left leg, hip and groin, up to the level of the tenth dorsal segment (fig. 3). Temperature sense was slightly impaired over the same area. The right leg could be moved freely showing that the pyramidal tract had not suffered.

September 17: There had been no pain since the operation. On this day, she began walking a little with assistance. This was the first time she had been up and about for two years.

September 26: The patient was discharged, free from pain, and not having taken morphine since the operation.

She remained free from pain on the left side, but in November, 1923, she began to have pain in the right foot and leg. This became severe in June, 1924, so that she reentered the hospital to have the other side of her cord incised. This was accomplished at the level of the previous operation under procaine hydrochloride anesthesia on July 2, 1924.

Fig. 3 (case 1).—Analgesia after first cordotomy at level of seventh dorsal spine.

July 25: She was discharged free from pain. Analgesia extended up to a rather indefinite level between the seventh and tenth dorsal segments, but was much more complete on the left side (fig. 4).

March 5, 1925: She returned to the hospital complaining of pain again on the right side in the hip and thigh. Evidently the last cordotomy had not been complete. Examination showed complete analgesia on the left side as before, but on the right it was complete only over the sacral segments, the area above this up to the ninth dorsal being somewhat hyperesthetic.

March 12: The third cordotomy was performed. The old incision was reopened with the patient under procaine hydrochloride, and the left anterolateral tract once more incised after including it within the special curved hook.

April 11: She was discharged. Analgesia now extended up to the third lumbar segment on the right side (fig. 5).

She returned once more to the hospital on Oct 25, 1926. The pain had been relieved until six months previously, since when it had returned, not only on the right, but to some extent in the left leg as well. Sensory examination at this time showed an unaccountable alteration of the observations previously recorded. There was complete analgesia of the right leg below the knee, and in this area

Fig. 4 (case 1).—Partial and complete analgesia after second cordotomy.

she had no pain. On the left there was now only partial analgesia over the thigh and lower part of the abdomen, while the left leg below the knee was actually hyperesthetic (fig. 6).

Nov. 4, 1926: A fourth cordotomy was undertaken with the patient under procaine hydrochloride and gas-oxygen anesthesia. At this session, bilateral sections of the cord were made at the former level after going through the old operative scar. She was discharged on November 28. Sensory examination showed that she once more had a complete analgesia on the left side up to the eleventh dorsal segment, but on the right it was complete only over the sacral and lower lumbar levels. There was no pain on the left side, but at times a very slight pain in the right hip.

This slight pain in the right hip continued and was sufficiently annoying so that it was decided to make one more attempt to section all the fibers of the left tract.

June 14, 1927: The fifth and final cordotomy was performed with the patient under procaine hydrochloride and gas-oxygen. The upper part of the old scar was reopened, and in addition, the fifth and sixth dorsal spines and laminae were removed in order to get a fresh field in the cord. On this occasion a narrow, straight knife was substituted for the curved hook and knife, the anterolateral tract on the left side being incised to a depth of nearly 4 mm.

July 13: She was discharged entirely free from pain on both sides. Sensory examination showed complete bilateral analgesia up to the ninth dorsal level (fig. 7).

Up to the present time (October, 1928), she has remained free from pain.

Fig. 5 (case 1).—Extent of analgesia after third cordotomy.

*Comment.*—This long suffering and extraordinarily patient woman deserved to have an easier road to a painless existence than was meted out to her. Certain important lessons, however, may be drawn from a backward glance over her record. In the first place, a bilateral cordotomy no doubt should have been performed at the original session, as her underlying condition involved both sides of the spine, although pain was confined to the left hip and leg. If the almost inevitable progression had been foreseen she might have been saved at least one of her operations. Secondly, this case illustrates well the difficulty of including all

of the anterolateral tract fibers within a curved hook 2.5 mm. deep. It was not until a straight knife was inserted to a depth of nearly 4 mm. that satisfactory anesthesia was finally, and it is to be hoped, permanently, secured. Lastly, it is a rather favorable comment on the efficacy of the procedure that a patient should return voluntarily four times for a repetition of the operation.

The second case was that of one of several syphilitic persons in the series. The patient was referred from the medical service after prolonged courses of antisyphilitic treatment had failed to relieve his pain.

Fig. 6 (case 1).—Change in sensory fields just before fourth cordotomy.

**CASE 2.—History.**—S. B. F., a man, aged 59, referred by Dr. O. G. Tinkham of Boston, was admitted to the hospital on Feb. 11, 1924, complaining of "lightning pains in legs and shoulders." He had acquired a gonococcal and syphilitic infection at the age of 20. In 1911, at the age of 46, he began having lightning pains in the body, arms and legs. In 1917, his condition was first diagnosed as tabes, and he was given a course of treatment although his Wassermann reactions of the blood and spinal fluid were negative. There was some improvement in his pain and in his general symptoms. He had been intermittently incontinent for two years before this treatment. From 1917 to the time of his admission to the hospital, he had had many intravenous and intraspinal arsenical treatments, as well as courses

of mercury, and iodides. His general symptoms progressed only slightly but his pains became gradually more severe.

*Physical Examination.*—His right pupil was larger than the left, and neither showed any reaction to light. There was loss of muscle sense in both lower extremities, and he was incontinent of urine. He had a positive Romberg's sign and a typical tabetic gait. The knee and ankle reflexes were absent bilaterally. Varicose veins were present in both legs and the right leg was edematous.

*Operation.*—Feb. 27, 1924: First stage laminectomy for cordotomy was performed with the patient under ether anesthesia. The operation was carried only

Fig. 7 (case 1).—Bilateral complete analgesia after fifth cordotomy.

to the exposure of the dura, as the patient's blood pressure fell unaccountably to 70 mm. over 58 mm. during the initial stages of the procedure. The spines and laminae of the fifth, sixth and seventh dorsal vertebrae were removed. Closure was then made in layers with fine silk.

*Second-Stage Operation.*—March 1, 1924: Bilateral cordotomy was performed with the patient under novocain anesthesia. The wound was reopened and the dura incised. A thick, opaque and extremely adherent arachnoid membrane presented. This had to be dissected away carefully from the cord and from the posterior roots. The anterolateral tracts were sectioned on both sides at a point about on a level with the sixth dorsal spine. Frazier's curved needle and knife were used,

the tracts being included to the full depth of 2.5 mm. The patient's legs were tested on the operating table immediately after each section. He said he felt no pain on either lower leg after vigorous pin-pricks.

He made a rather slow general recovery from the operation. For several weeks his legs were swollen, and he complained of "dull aching" in the legs. He had, however, none of his old shooting pains. The pain in his shoulders was of course uninfluenced by the operation. His bladder became infected and he had to have constant drainage and irrigations. He was up and walking about by May 1. His legs seemed somewhat generally weak, but were probably no more so than could be accounted for by his long sojourn in bed together with their previous general

Fig. 8 (case 2).—Areas of partial and complete analgesia after cordotomy at level of sixth dorsal spine.

weakness. For a short time he lost control of his rectal sphincter, but this gradually returned. He was discharged May 5, well pleased with his result. On June 3, 1924, his wife reported that he had no pain in his legs. His area of anesthesia, on discharge from the hospital, is shown in the chart (fig. 8).

*Comment.*—This patient has been lost sight of despite several attempts to follow up the case; therefore, the final result is unknown. He was relieved of the lightning pains in his legs from March 1 to June 3, 1924, a period of three months, and this although the area of analgesia

was complete only in the left leg below the knee, and partial up to the eighth dorsal segmental level. The case illustrates a fact which was true of other syphilitic persons in the series, namely, that after an operation on the spinal cord an existing urinary or bowel sphincter difficulty may be made considerably worse temporarily.

The third case to be reported was the only one of the kind in the series, namely, an inoperable, recurrent tumor of the spinal cord.

*CASE 3.—History.*—E. V. K., a woman, aged 39, referred by Dr. R. Hinchey of Waltham, Mass., was admitted to the hospital on April 4, 1924, complaining of pain down both legs. She had been operated on at the Peter Bent Brigham Hospital in August, 1922. At that time, a diffuse, vascular tumor was disclosed in the lumbar region of the cord. Fragmentary removal only was possible as the growth involved extensively the nerve roots on the right side. Both before and after this operation she had pain down the right leg. This continued despite intensive deep roentgen therapy. Finally she was given morphine in increasing amounts, and at the time of her present entry she was having 8 grains (0.52 Gm.) daily. Even this huge dose failed to relieve her more severe attacks of pain, which were now not only down the right leg but in the left as well. Her general condition seemed good enough to warrant a life expectancy of at least six months.

*Operation.*—April 17, 1924: Bilateral cordotomy was performed with the patient under ether anesthesia. The spines and laminae of the third to the sixth dorsal vertebrae were removed. The arachnoid was thick and adherent to the cord. The anterolateral tracts on both sides were sectioned at a level between the fifth and sixth dorsal spines. Both incisions were performed with Frazier's curved hook and knife to the depth of 2.5 mm.

April 18: Examination showed complete analgesia up to the seventh dorsal segment (fig. 9). She had no pain in her legs, but required morphine for pain at the site of operation.

April 22: Morphine was reduced to  $\frac{1}{3}$  grain (0.0216 Gm.) from every six to ten hours, whereas before operation she had required  $\frac{3}{4}$  grain (0.0486 Gm.) every three hours.

April 24: From this date onward no morphine was required. She had to be catheterized twice daily.

April 27: A severe cystitis developed and the patient was put on constant drainage. On this date also she showed signs of a hypostatic pulmonary complication.

The patient's bronchopneumonia became aggravated and she died on May 3. Up to the last, she had none of her old pain down the legs.

*Comment.*—The judgment used in this case was obviously at fault. Either the patient was in no condition to undergo an operation or her expectancy of life was much shorter than had been surmised. She was, at all events, the one patient in the series for whom operation hastened death, there being perhaps slight consolation from the fact that her pain was relieved and that she required practically no morphine for the two weeks she survived.

The fourth case is perhaps the most satisfactory in the series, and may be termed a perfect result.

CASE 4.—*History*.—H. P. P., a civil engineer, aged 50, was admitted to the hospital on Jan. 5, 1926, complaining of attacks of pain in the left flank. He was referred to the N. E. Deaconess Hospital by Dr. A. A. Cushing of Brookline, Mass. He acquired a syphilitic infection in 1912, and at that time received a course of treatment. In 1920 and 1922, and also at the time of his admission, the Wassermann reactions of the blood and spinal fluid were negative.

In February, 1925, he had an attack of pain in the region of the left kidney. This was diagnosed as renal colic, and lasted three days. A similar attack occurred in July, 1925, which lasted one week and was characterized by severe

Fig 9 (case 3).—Bilateral complete analgesia after cordotomy at level of fifth dorsal spine.

pain associated with vomiting. Morphine was necessary for relief. Complete genito-urinary as well as gastro-intestinal studies were negative in September, 1925. Intermittent attacks of the same type of pain occurred from July, 1925, to January, 1926, and slight pain in the left loin was present constantly. At the time he entered the hospital he was having a severe attack which had lasted two weeks. He was entirely incapacitated from work. He was seen by Dr. J. B. Ayer who believed that nothing further in the way of relief could be accomplished from the medical standpoint. In his opinion, the painful attacks were some type of renal or intestinal crises due to syphilis. Cordotomy was advised and accepted.

*Operation.*—Jan. 8, 1926: Right-sided cordotomy was performed with the patient under ether anesthesia. The spines and laminae of the second, third and fourth dorsal vertebrae were removed, and the dura incised. The arachnoid, as in all syphilitic persons, was found to be greatly thickened, opaque, and adherent everywhere to the cord. Section of the right anterolateral tract was made with the curved hook and knife to a depth of 2.5 mm. at a level corresponding to that of the third dorsal spine.

January 9: The patient was entirely free from pain such as he had prior to operation. There was some discomfort in the vicinity of the site of operation.

Fig. 10 (case 4).—Extent of analgesia after unilateral cordotomy at level of third dorsal spine.

There was no apparent weakness of the right leg. The deep reflexes were equal and normal at both knees and both ankles.

January 14: He was entirely free from all pain. He had some difficulty in voiding and had to be catheterized daily. Two days later, he was voiding spontaneously. On January 18, he was sitting up in bed. The stitches were removed on this day, and the wound found to be healed perfectly. On January 24, he was walking about the ward. He was conscious of no weakness of the right leg and had no pain whatever. He was discharged home on this day. Analgesia was complete on the left side up to the level of the tenth dorsal segment, and partial for one segment higher. Thermal sense over the same area was impaired, extremes of temperature being recognized, but warm and cool not differentiated (fig. 10).

Feb. 11, 1928 (two years after operation): The patient came in for examination at request. He was in excellent spirits and had been at work steadily since two months after his operation. He had had no attacks of his previous pain. Sensory examination showed absolute loss of pain and thermal sensation below the tenth dorsal level on the left side. He was immensely grateful, and said that he would have been "finished" but for his cordotomy.

*Comment.*—The interesting feature of this patient's story, aside from the satisfactory result of treatment, is confined to speculation as to the nature of his attacks of pain. After careful urinary and intestinal tract studies, no abnormalities were disclosed and there has been no subsequent evidence in other ways of a pathologic condition in either system. It has been assumed, therefore, that Dr. Ayer's diagnosis of "renal crises of luetic origin" was the most plausible explanation of the phenomena.

The following case, the fifth in the series, was referred by Dr. Ayer shortly after he had witnessed the successful outcome of the preceding patient. Disappointment, however, instead of success was in store, and this without a technically accountable reason.

*CASE 5.—History.*—T. F. K., a business man, aged 46, was admitted to the hospital on Jan. 20, 1926, complaining of pain, particularly in the legs, but also in the trunk and arms to a lesser degree. He had pleurisy at the age of 19, and a roentgenogram taken in 1923 showed an old fibrosed process in the left lung. In 1898, he had a "sore throat" which was diagnosed as syphilitic, and he was treated with mercury and iodide. He said that he had not had a primary lesion. In 1913, his condition was diagnosed tabes dorsalis, and since that time he had had many vigorous and prolonged courses of antisyphilitic treatment. In 1920, he began having lightning pains in his knees. These pains continued, although at times they were somewhat reduced in intensity, and were always most persistent and severe in the lower extremities. He had lost much sleep and had had to be away from business a great deal because of pain. His vesical and rectal sphincters were becoming spastic.

*Physical Examination.*—A considerably emaciated man with Argyll Robertson pupils, absent knee reflexes and a slightly positive Romberg's sign was seen.

*Operation.*—Jan. 23, 1926: Bilateral cordotomy was performed with the patient under procaine hydrochloride and gas-oxygen anesthesia. The spines and laminae of the first, second and third dorsal vertebrae were removed, and after opening the dura, the usual thickened, adherent and meshlike arachnoid of the syphilitic person was disclosed. The cord itself appeared normal. The antero-lateral columns were sectioned on both sides by inserting the curved hook to its full depth of 2.5 mm. and dividing the fibers contained therein. On the right, the section was made at about the level of the first dorsal spine, and on the left, approximately 1 cm. lower.

January 24: Examination revealed complete loss of pain sense over both legs, hips and lower part of the abdomen up to the lower end of the dressing. He could move both legs freely in all directions.

February 1: He had two or three very uncomfortable days following operation, but on this date was fairly comfortable. He complained of peculiar sensations in his legs, but did not have his former pain. He had to be catheterized twice daily.

February 4: Sensory examination was carried out completely and revealed total analgesia up to the tenth dorsal segmental level on the right and to the eleventh dorsal on the left, except for slight patch in the left groin (fig. 11).

February 18: He had been up and about for ten days. He walked as well as ever, and was conscious of no weakness of his legs. He had gained 2.6 Kg. in weight. His bowels and bladder were improving.

February 24: He was discharged. Catheterization was still necessary occasionally. He had gained 3.6 Kg and was free from his old pain.

May 26: The patient was seen at his home. He had become greatly discouraged because he said the pains in his body and legs had returned except below

Fig. 11 (case 5).—Extent of analgesia twelve days after cordotomy at level between first and second dorsal spines. Shaded area in left groin not analgesic.

the knee on the right side. Sensory examination showed at this time a considerable shrinkage of the analgesia which had been present shortly after the operation, the area of total loss of pain sense now being confined to the right leg below the knee, i. e., the area where he was not having spontaneous pain (fig. 12).

Jan. 18, 1928: On this date, two years after cordotomy was performed, the patient reported for examination by request. He said that his pains were just as severe as before operation, except in his right thigh, where examination showed complete analgesia. He still had slight hypesthesia to pain over the right lower leg and over the left groin and thigh, but the left lower leg showed normal sensation (fig. 13). He had been at business steadily, however, during the past year.

*Comment.*—This case must be classed as a failure, but there are nevertheless several interesting features in it for which explanation is wanting. It is, for instance, difficult to see why the patient's original practically complete analgesia should have faded out as it did after the lapse of less than four months. It is equally disconcerting to explain the further change in his sensory chart after two years, with a shift in the totally analgesic area from below the right knee to the area of the right thigh. Furthermore, when he reported in 1928, he seemed to be

Fig. 12 (case 5).—Marked recession of analgesia four months after cordotomy.

in a much less despondent mood than he had been after his operation, and it was hard to see how he could have attended business regularly for a year if his pains had been as disabling as they had been previously.

It was a year and three months after this discouraging experience before another cordotomy was attempted, and although the next case cannot be called perfect, it was nevertheless highly satisfactory and the operation worth while.

CASE 6.—*History*.—C. C., a laborer, aged 48, referred by Dr. W. C. Quinby from the genito-urinary service of the hospital, was admitted to the hospital in March, 1927, complaining of pain in the left side and down the left leg. He had been admitted previously, on Jan. 8, 1926, complaining of blood in his urine. Exploration of the region of the kidney at that time had revealed an inoperable hypernephroma. The left kidney was removed together with some tissue from the tumor. He began having pain in the left side, hip and thigh, in September, 1926, which continued with increasing severity. He had to give up work because of the pain, and for two months before admission required sedatives in order to be able

Fig. 13 (case 5).—Further change in sensory fields two years after cordotomy.

to sleep. Roentgenograms of the spine showed destruction of the transverse processes of the first and second lumbar vertebrae, together with recurrence of the hypernephroma. Pain was uninfluenced by roentgen therapy. Exploration of the upper lumbar spine by Dr. Quinby on March 15, 1927, revealed extensive involvement by the tumor. The tissues were so vascular that section of the posterior roots at this level could not be accomplished. About March 31, the pain shifted from the left to the right leg.

*Physical Examination*.—The patient was a considerably emaciated man in obvious pain, lying in bed. Both legs could be moved weakly and both showed moderate generalized atrophy. The left thigh was slightly hypesthetic, but there were no other sensory changes. The knee reflexes and all other deep reflexes were exaggerated but equal on the two sides.

*Operation.*—April 15, 1927: Bilateral cordotomy was performed with the patient under ether anesthesia. The fourth, fifth and sixth dorsal laminae were removed. The dura and arachnoid appeared normal. Section of the anterolateral tracts on either side was made at about the midportion of the exposed field, i. e., at the level of the fifth dorsal spine. On each side the incision was made with a narrow pointed knife, the blade of which was introduced to a depth of 3.5 mm.

April 17: The patient had immediate and complete relief from the pain in his legs after operation. His leg movements were the same as before. He had retention of urine for thirty-six hours. Knee reflexes were absent on this date, but the

Fig. 14 (case 6).—Complete analgesia after cordotomy at level of fifth dorsal spine.

achilles reflexes were equal and normal. There was complete loss of pain sense bilaterally up to the level of the tenth dorsal segment (fig. 14).

April 29: The patient was comfortable and happy. He sat in a wheel chair and felt no pain.

May 17: He was discharged to a convalescent home. His legs were weak, but no more so than before operation. He had no pain whatever. Sensory changes were unchanged since the examination of April 16.

Jan. 20, 1928: On this date, nine months after operation, the patient was seen at his home. After leaving the Brigham Hospital, he was in a convalescent hospital until Aug. 1, 1927. He then went home, was up and about and felt well until

about Nov. 1, 1927. At this time he began having a moderate degree of pain in his back at the site of the exploratory laminectomy in the upper lumbar region. Examination showed that this area was bulging, tense and tender, and it was evident that his tumor was growing rapidly, spreading out through the place of least resistance posteriorly. He had no pain in his hips or legs. Sensory examination showed a complete loss of pain sense up to the tenth dorsal level as before. Thermal anesthesia was complete on the left side, but on the right hot and cold were distinguished as cool and warm. He continued to have pain in the region of the recurrent growth until his death several months later, but never had pain down the legs.

*Comment.*—There can be hardly any question but that a cordotomy was indicated in the case just described. It gave the patient immediate relief from all pain, enabled him to get along without drugs and to be up and about for several months until extensive recurrence finally caused him to become worse again. It is probable that the reason he had pain subsequently at the site of the growth was because segments higher in the cord than those covered by the actual analgesia were involved, and for this reason, no doubt it would have been wiser and more far-sighted to have performed the section at a level above the fifth dorsal spine originally.

The next case to be described was that of another of the several syphilitic patients in the series. Again the result was not all that was hoped for, but might be classed as distinctly satisfactory.

*CASE 7.—History.*—E. P., a man, aged 44, referred by Dr. E. H. Taylor of Pittsfield, Mass., was admitted to the hospital on Aug. 8, 1927, complaining of periodic "pains in the stomach and legs." He had had pains in his legs for thirteen years at intervals of a few weeks. These were sharp and shooting, at first rather slight, but gradually increased in severity. He said that he had not had gonorrhea and syphilis but in 1920 he had a positive Wassermann reaction of the blood. He was given antisyphilitic treatment for a year after this discovery, but had no relief from his pains. The Wassermann reaction, however, became negative. For four years he had had pain in his abdomen, which came in periodic attacks at intervals of about one month. These attacks became so frequent and so severe that the patient tried to commit suicide. Three years before admission he was given another course of antisyphilitic treatment at a Boston hospital without affecting the pain.

*Physical Examination.*—Argyll Robertson pupils, slight general hypesthesia over the entire left side, most marked in the hand and foot were noted. The patient had a slightly positive Romberg's sign. The knee and ankle reflexes were absent bilaterally. Between August 8 and 13, 1927, while in the hospital, he had four attacks of pain in the abdomen. The pain was apparently extreme, and associated with vomiting, pallor and sweating. Morphine in repeated  $\frac{1}{4}$  grain (0.0162 Gm.) doses was required for relief.

A diagnosis of tabes dorsalis with gastric crises was made, and cordotomy advised.

*Operation.*—Aug. 13, 1927: Bilateral cordotomy was performed with the patient under procaine hydrochloride anesthesia. The spines and laminae of the first, second and third dorsal vertebrae were removed. The dura appeared normal. The

arachnoid was thickened, opaque and gray, forming almost a mesh around the cord. Section of the anterolateral columns was performed with the curved needle and knife to a depth of 2.5 mm. On the right the section was made at a level between the first and second dorsal spines, on the left at the level of the second dorsal spine. The patient complained of momentary pain only when the fibers farthest anterior were being sectioned. After each section the patient's sensation on the opposite side was tested with a pin, and complete analgesia was demonstrated up to the level of the fifth dorsal spine.

Fig. 15 (case 7).—Partial analgesia after cordotomy at level of second dorsal spine.

August 27: The patient was uncomfortable for three days after operation, requiring morphine at times, but his improvement after the third day was rapid and most satisfactory. He had no further attacks of abdominal pain, but did have occasional slight pains in his legs. His sphincters were not upset. He had a definite feeling of warmth in both legs for about two weeks after operation. His appetite improved enormously, and he said that he now looked forward to eating as he had not done for eight years. He was discharged on this date in excellent spirits and extremely grateful.

Sensory examination just before discharge showed that he did not have the complete loss of pain sense which was demonstrated on the operating table just after section of the fiber tracts. There was nearly complete analgesia and loss of

thermal sense over the trunk and left leg, and over the right leg below the knee, but over the right thigh there was only slight hypesthesia and over the left lower part of the chest there was a patch of actual hyperesthesia (fig. 15).

April, 1928 (nine months after operation): The patient reported by letter saying that he felt "pretty good," and that "since the operation I have had no pain in my stomach." He was still having occasional pains in his legs, but "not so strong as before. I have a good appetite now, I sleep pretty good and I have gained 15 lbs."

*Comment.*—This patient was well satisfied with the result of his operation, although physiologically the section of his tracts was not complete. He had, at all events, returned to a useful and enjoyable life, entirely free of his major trouble, the gastric crises.

The next case presented features somewhat similar to those recorded in case 5. The patient, a syphilitic patient, had stopped work five years before admission because of recurring attacks of pain in the back. Like the former patient, he was benefited for a short while after the first cordotomy, but the pain returned and a second cordotomy was performed as he did not have complete analgesia. After this second operation he had a further temporary cessation of pain which subsequently recurred. Unlike the patient in case 5, however, this patient's analgesia remained complete after the second cordotomy.

CASE 8.—*History.*—F. E. B., a man, aged 45, referred by Dr. Loring Grimes of Swampscott, Mass., was admitted to the hospital on Oct. 27, 1927, his chief complaint being pain in the back, but he also had some pain in the legs. He had had pain in the back for from ten to twelve years. During the earlier years the pain had been of short duration, coming in attacks two or three times a year. Six years ago the attacks came every two or three months, lasting a day or two at a time. He was confined to bed during the attacks. Five years ago he was obliged to give up work because of the frequency and the severity of the pains. During the past year he had had attacks of pain coming on every seven days and lasting three to four days.

His first admission to the hospital was in June, 1926. At this time he was having periodic attacks of pain in the lower part of the back which had been uninfluenced by ordinary measures or by orthopedic treatment. Roentgenograms of the urinary system were negative, but those of the spine showed hypertrophic arthritic changes. Lumbar puncture, however, showed a markedly positive Wassermann reaction, and some observers thought that his pupillary reflexes were sluggish to light. He was therefore transferred to the medical service for treatment for cerebrospinal syphilis. He was given this treatment from June to September, 1926, without relief from pain. He was then admitted to the surgical service for cordotomy. The Wassermann reaction of the spinal fluid remained positive. He had lost from 60 to 70 pounds (27.2 to 31.8 Kg.) during the last year or two.

*Physical Examination.*—An area of extreme, painful hyperesthesia over the lower thoracic region posteriorly was noted. There was tenderness to pressure over the dorsal and lumbar spine. Roentgenograms of the spine were negative save for slight arthritis spurs. Cordotomy was advised and accepted.

*Operation.*—Nov. 3, 1927: Bilateral cordotomy was performed with the patient under procaine hydrochloride anesthesia. The spines and laminae of the first, second and third dorsal vertebrae were removed, and the dura opened over the area thus exposed. The arachnoid was greatly thickened and almost completely opaque, so that the cord could not be seen through it. On opening the arachnoid, it appeared like a mesh of loose tissue adhering slightly at many places to the cord and nerve roots. The right anterolateral tract was sectioned by use of the curved hook and knife to the full depth of 2.5 mm. at the level of the second dorsal spine. The patient complained of severe pain for a few seconds at the time of section. The left leg and lower trunk were tested immediately afterward and found to be

Fig. 16 (case 8).—Partial analgesia after first cordotomy.

anesthetic. Section of the left tract was made entirely with a narrow, pointed knife, at a level perhaps 1 cm. below the incision on the right. The right leg and lower trunk were found to be anesthetic after this incision.

November 19: The patient was discharged. For about one week after operation he complained of occasional "lightning pains" in both legs, but these gradually ceased. At the time he left the hospital he was sitting up in a chair, without pain, and was cheerful and greatly pleased with the result of the operation. The hyperesthetic area in the back disappeared immediately following operation. He did not have a complete analgesia, however. On the left side, pain and temperature sense were nearly completely lost up to the fifth dorsal level, but on the right the same area was only moderately hypesthetic (fig. 16).

March 15, 1928: On this date the patient was readmitted to the hospital because of a return of pain in the middle of the back. He had been comfortable and free from pain for about five or six weeks after operation. Sensory examination showed that he had only slight dulling of pain and temperature sensations up to the previous level. It was thought best to see if a more complete tract section could be obtained by another cordotomy.

*Second Operation.*—March 28: Bilateral cordotomy was performed with the patient under procaine hydrochloride anesthesia. The original area was exposed through the old operative scar. The tract on the right side was exposed after

Fig. 17 (case 8).—Complete and partial analgesia after second cordotomy at level of second dorsal spine.

division of one sensory root in order to get better access. The narrow, pointed knife was used for the section which was carried to a depth of from between 3 and 4 mm. The same procedure was carried out on the left, the section on this side being at least 4.5 mm. deep. After each section, the opposite side of the body was tested and found to be anesthetic up to the umbilical level.

April 11: The patient was again discharged. His convalescence had been uneventful except for occasional shooting pains in his legs such as he had had after his first cordotomy. He was entirely free from pain in the back; there was no loss of power in his legs and no disturbance of the sphincters. Examination now showed a complete loss of pain sense and a nearly complete loss of temperature sense up to the fifth dorsal segmental level (fig. 17).

*Comment.*—It was confidently expected that this patient had been relieved permanently by his second operation. He reported, however, on Aug. 8, 1928, saying that within a month or two after the last operation the pain in his back had returned and continued as previously with the exception that it came only if he moved around or tried to do any manual work. He had gained from 20 to 30 pounds (9 to 13.6 Kg.), was eating and sleeping well, and did not have the anxious, tired expression he had previously worn. Examination showed a bilateral complete analgesia, with fairly complete temperature loss up to the fifth dorsal level. The patient's sister was convinced that he did not have the pain which he claimed, and his whole picture was certainly decidedly different from that which he had presented before the operations. He had not worked for five years, and had made no serious attempt at any kind of a livelihood after either cordotomy.

#### COMMENT AND CONCLUSIONS

Little can be added in a general discussion of these cases that has not been referred to already in the individual comments, and the series is plainly too small to admit of any but the simplest conclusions. Of the eight patients, six were distinctly benefited by the operation of cordotomy and two were apparently not relieved except for periods of a month or two. One death occurred as a result of a postoperative pulmonary complication. In five patients, the operation was performed because of pain due to a previous syphilitic infection. Three of the patients were relieved, in two of whom the chief pain was due to some form of abdominal "crises." The two who were not relieved had the typical "lightning pains" of tabes. In one of the latter, the faulty result may be attributed to an incomplete tract section, but in the other the anterolateral columns were apparently completely incised as shown by the resultant analgesia. Of the three patients who did not have syphilis, in one the pain was due to a chronic hypertrophic spondylitis, in another to a recurrent tumor of the spinal cord, and in the third to erosion of the spine and pressure on the posterior roots by a hypernephroma. In all of these, relief was obtained by the operation.

One point particularly comes up in relation to the operative technic, namely, the depth of the cord incision. It is my impression that the 2.5 mm. depth obtained by the curved hook of Frazier is perhaps adequate in the middorsal region, if the hook is placed with absolute exactness. For the upper dorsal region, where the cord is slightly larger, and even in the middorsal area, if placement is not perfect, this depth is hardly sufficient. In order to get the fibers situated farthest anteriorly and medially, it has been necessary to do one of two things, either to make a secondary inclusion of the inner fibers with the hook, or to use

a narrow, pointed knife for the section, carrying the point inward sometimes to a depth of 4 mm.

A word should be said also regarding the possibility of determining the anatomic relationship of the fibers in the anterolateral tracts. It is my impression from such evidence as is presented in this series, especially from the study of case 1, in which it was necessary to make several successive sections of the cord, that the most superficial fibers in the tract represent the lowest, i.e., the sacral levels, and that the fibers for the segments progressively higher lie respectively deeper in the tract. This is merely a deduction from the fact that apparently the greater the depth to which the cord incision was made, the higher the level of the analgesia on the opposite side of the body became. If this is true, it probably means that the fibers of these tracts starting from the lowest levels and working upward after crossing in the cord take a position in the opposite anterolateral tract medial to those which have entered just previously, thus pushing these earlier entering fibers outward toward the periphery of the cord.

# EXPERIMENTAL DIABETES INSIPIDUS\*

E. B. TOWNE

During the past twenty years, a great deal of experimental work has been done in attempts to clear up the mysteries surrounding the functions of the pituitary gland. Many of the problems which seemed to have been solved by the early work of Paulesco, and especially by the extensive investigations of Cushing and his associates, have been opened again by the work of Camus and Roussy and their followers, who attribute to nerve centers in the hypothalamus most of the functions which were previously proved, as it appeared, to belong to the hypophysis. Even the question whether the gland is essential to life, as believed by Paulesco and Cushing, has been denied from the start by many, including Handelsmann and Horsley, Aschner, Sweet and Allen, and more recently by Brown, and Dandy and Reichert. This paper deals with another open question: Is diabetes insipidus, which is clinically associated with tumors involving the hypophysis and the floor of the third ventricle, due to disturbance of the function of the gland, or to injury of nerve centers in the floor of the ventricle? A study of the literature makes it evident that conclusions cannot be based on experimental polyurias of short duration, owing to the fact that numerous types of operative damage to the pituitary gland, to the floor of the third ventricle or even to more distant parts, as the floor of the fourth ventricle,<sup>1</sup> caused polyurias lasting from a few days to a few weeks. There are only six experimental observations in which the polyuria lasted four months or more. The first object of this investigation was to produce, if possible, a truly permanent polyuria. All evidence suggested that the most promising method would be division of the stalk, high enough to detach all epithelial cells of the pituitary gland from the base of the brain, leaving the gland itself in situ.

The pituitary gland of the dog is attached by its stalk to the floor of the third ventricle at the tuber cinereum. It contains two types of epithelial cells. The pars anterior is made up of cells, some of which contain granules having affinity for acid or basic stains, grouped around blood sinusoids. The remainder of the epithelium surrounds the pars posterior and the stalk, and spreads out for a variable distance over the floor of the third ventricle. That portion which surrounds the posterior

---

1. Kahler, O.: Die dauernde Polyurie als cerebrales Herdsymptom, *Ztschr. f. Heilk.* 7:105, 1886.

lobe is called *pars intermedia*, and that which surrounds the stalk and extends onto the base of the brain is called *pars tuberalis*. Microscopically, the *pars intermedia* and *pars tuberalis* are identical, consisting of epithelial cells without granules, often arranged about alveoli containing colloid material. There is not any histologic reason for a belief that the function of the *pars tuberalis* differs in any way from that of the *pars intermedia*, if either has a function. The gland has a double supply of blood, from vessels that come down the stalk, and from an artery that enters the posterior lobe from the adjacent dura. There is a potential anastomosis between the two systems, which gives all parts of the gland an adequate supply of blood from the posterior artery, after division of the stalk. If the *pars anterior* is a gland of internal secretion, and the *pars intermedia* and *tuberalis* secrete directly into the third ventricle, a division of the stalk at the base of the brain, detaching all *pars tuberalis* cells, would theoretically eliminate secretion from the *pars intermedia* and the *pars tuberalis*, and interfere only temporarily, if at all, with the secretion of *pars anterior*. This would leave out of account the possibility of accessory hypophyses, such as that described by Dandy and Goetsch<sup>2</sup> between the layers of the dura in the sella turcica, but it was felt that if the technical difficulties of detaching all cells of the *pars tuberalis* could be overcome, a permanent polyuria might result.

The cells of the *pars tuberalis* on the base of the brain have been a serious stumbling block in experimental surgery of the pituitary gland. "Total" hypophysectomy has had two meanings. Aschner<sup>3</sup> and Sweet and Allen<sup>4</sup> assumed that these cells lack physiologic importance. Crowe, Cushing and Homans<sup>5</sup> noted that a few cells of the *pars intermedia* are found adherent to the under surface of the third ventricle in every total hypophysectomy. Dandy and Reichert<sup>6</sup> had seven "histologically proven total extirpations," but this means that the base of the brain was studied for "microscopic remnants of the anterior lobe, and in none were any found." They do not say that there were no

cells of the pars tuberalis. Brown<sup>7</sup> had five animals in which "no trace of hypophysis was found microscopically," but he did not say specifically that cells of the pars tuberalis were not present on the base of the brain, and it seems possible that he also disregarded these cells. Handelsmann and Horsley<sup>8</sup> operated on fifty-four animals, in fifteen of which the gland was completely removed—"that is, we could not find even cells of the pars intermedia infundibuli." They qualified even these total hypophysectomies. "We say so called complete removal of the gland because very possibly there is in some cases an accessory gland in the canalis cranio-pharyngealis which perhaps becomes hyperactive when the gland is removed." They are the only ones, among the many who have worked on this problem, who clearly stated that it is impossible to ignore the pars tuberalis and accessory hypophyses in extirpation experiments. Exactly the same conditions hold true in divisions of the pituitary stalk. Unless all cells are detached from the base of the brain, the results cannot be safely interpreted; and even when this is accomplished, the difficult matter of eliminating accessory glands remains.

#### EXPERIMENTS

Ten dogs were operated on by the left temporal route of Paulesco. Gentle traction was applied to the stalk with a blunt hook, and an incision was made in the base of the brain to detach the stalk. Four animals died within a few days, and six lived in good health until killed after their polyuria had terminated. The animals were kept in metabolism cages for one week prior to operation, and for three or four successive days of each week after operation. They always had a plentiful supply of drinking water. The urinary output was measured at the same hour each day. Each of these six animals showed a postoperative polyuria which lasted for at least four weeks; but the urinary output became approximately normal in all cases. The longest period of polyuria was twenty-one weeks. When the polyuria had ceased for two weeks or more, the animal was killed with chloroform, and the brain was fixed in situ by injection of the carotid arteries with 4 per cent formaldehyde. The pituitary gland, the adjacent base of the brain and a portion of the base of the skull were removed in one piece and placed in formaldehyde for seven days; then the dura of the sella with the gland, its stalk and the attached base of the brain were cut in sagittal serial sections. Accessory hypophyses were not found in the dura of any

of these animals. The serial sections of the hypophysis and base showed that the division of the stalk had been high enough to detach all cells of the pars tuberalis in only one animal. This dog's polyuria lasted twenty-one weeks. Small groups of cells had been left attached to the under aspect of the floor of the third ventricle in all the other five animals. The average duration of polyuria in this group was nine weeks. As neither the clinical nor the necropsy observations in these five dogs show any material differences, the protocols of only two experiments will be given. The first is of a typical example of the group of five dogs in which all cells of the pars tuberalis were not detached, and the second is of the one animal in which the object of the experiments was accomplished.

Dog 7.—A male mongrel, aged approximately 8 months, weighing 8.6 Kg., had an average urinary output of 185 cc. for seven days. On Jan. 21, 1920, an operation was performed under ether anesthesia. When the stalk was divided, a flow

Fig. 1 (dog 7).—Average daily urinary output in cubic centimeters for one week preoperative and twenty weeks postoperative.

of the cerebrospinal fluid did not occur, indicating that the incision had not entered the ventricle. For forty-eight hours after operation, the dog was well and took food and water freely. The output was 640 cc. on January 22, and 790 cc. on January 23. For the next six days, the animal was sick, and the output decreased, the lowest point being 60 cc. on January 27. After January 30, the dog was always well. Figure 1 shows the average daily urinary output for twenty weeks after operation. The average is usually based on the measurements of four consecutive days in the metabolism cage, but for a few weeks it is based on three days' output. The greatest amount in twenty-four hours was 1,175 cc. on March 6, in the seventh week. The polyuria declined after the seventh week to approximately normal in the eleventh, twelfth and thirteenth weeks. There was then a slight rise until the seventeenth week, after which the output remained normal. The dog's weight increased steadily, to 10.2 Kg. in the fifth, 13.8 Kg. in the ninth and 14.5 Kg. in the twentieth week. On May 20, the animal was killed with chloroform.

Serial sections (fig. 2) showed a dense band of scar tissue at the level of the incision. Below the scar was the pars anterior (a), which was made up almost entirely of eosinophilic cells; the pars nervosa (b), which was undifferentiated tissue invaded by cells of the pars intermedia, and the pars intermedia (c). Above

the scar, there were two large groups of epithelial cells, in normal relationship to the base of the brain. The anterior group (*d*) had the typical structure of pars tuberalis, most of the cells being chromophobe and many forming alveoli. However, about one tenth of the cells were eosinophilic, did not form alveoli and were not grouped about blood sinusoids. The posterior group (*e*) was made up of about two-thirds typical cells of the pars tuberalis, and one-third eosinophilic cells, not in relation to blood vessels. In brief, the cells of the pars tuberalis were not detached from the base of the brain in this case. The unexpected observation of eosinophilic cells typical of the pars anterior among the cells of the pars tuberalis was common to all these five experiments in which the incision was not made high enough to detach the pars tuberalis; they occurred in varying proportions, but were not so plentiful in any other as in this case, which is reported for that reason.

Fig. 2 (dog 7).—*a* indicates pars anterior; *b*, pars nervosa; *c*, pars intermedia; *d* and *e*, groups of cells of the pars tuberalis above operative scar.

Dog 4.—A female mongrel, aged approximately 6 months, weighing 6.1 Kg., had an average urinary output of 140 cc. for seven days. On Jan. 5, 1920, an operation was performed under ether anesthesia. The stalk was separated by an incision which entered the ventricle and gave a free flow of cerebrospinal fluid. On the first, second and third postoperative days, the animal was well, and the output of urine was 370, 595 and 610 cc. For the remainder of the first week, she was sick, and the daily output was about 200 cc. From January 13 onward, she was always in good health. Figure 3 shows the average daily output for twenty-four weeks after operation. The average is based on measurements for three or four successive days of each week in the metabolism cage. The largest twenty-four hour amount was 1,450 cc. on February 26, in the eighth week. The polyuria reached its peak in the ninth week. The output then decreased rapidly until the fifteenth week, rose slightly until the twentieth week and then dropped to normal

for three weeks. The dog's weight nearly doubled during the period of the experiment, reaching 12 Kg. in the twenty-fourth week. On June 24, the animal was killed with chloroform.

Serial sections showed that all cells of the pars tuberalis had been detached from the base of the brain by the operation. The floor of the third ventricle had been reformed by connective tissue, without ependymal lining, from *a* at the lower edge of the optic chiasm, to *b* in figure 4. The pars anterior (*c*) appeared normal, with about the usual proportion of chromophile and chromophobe cells. The pars nervosa (*d*) was atrophic and invaded by cells of the pars intermedia. The pars nervosa was surrounded by an empty space, and about this was a zone of cells of the pars intermedia. Posteriorly, these cells were separated from the base of the brain by scar tissue, but anteriorly, at the point where the normal floor of the ventricle joined the posterior end of the newly formed connective tissue floor, a mass of cells had invaded the base of the brain. This area is surrounded by a circle in figure 4 and shown in greater magnification in figure 5. Most of these were typical cells of the pars intermedia, arranged about alveoli containing colloid

Fig. 3 (dog 4).—Average daily urinary output in cubic centimeters for one week preoperative and twenty-four weeks postoperative.

material, but a few contained eosinophilic granules and were exactly like the eosinophil cells of the contiguous pars anterior. It was at first suspected that this mass of cells had not been detached, but a careful study of all the sections showed conclusively, from the location of the scar tissue, that this had been accomplished, and that the cells had reunited to the end of the uninjured floor of the ventricle. The final result was that a large number of cells of the pars intermedia were in perfectly normal relationship to the ventricle, through reattachment to the undamaged base of the brain.

#### COMMENT

These experiments failed to produce a permanent polyuria. Five times the operation did not detach all the cells of the pars tuberalis from the base of the brain; only once was this accomplished. The clinical result was the same in all cases, though the polyuria lasted a few weeks longer in the experiment which was technically successful. The most striking histologic observation was the invariable presence of eosinophilic cells, which do not belong there, in the nests of cells of the

Fig. 4 (dog 4).—*a* to *b* indicates newly formed connective tissue of floor of third ventricle; *c*, pars anterior; *d*, pars posterior. The circle surrounds the field shown in higher magnification in figure 5.

Fig. 5 (dog 4).—High power photomicrograph of the field encircled in figure 4. Junction of normal and connective tissue portions of floor of ventricle, showing invasion of base of brain by reattached pars intermedia.

pars tuberalis, which were left attached to the base of the brain in five experiments. Also, there were a few eosinophilic cells in that portion of the pars intermedia or pars tuberalis which became reattached to the uninjured base of the brain in dog 4.

Only six experimental observations in which a polyuria lasted four months or more were found in the literature. These were analyzed to see whether they would throw any light on the possible interpretation of the experiments here recorded. The result is summarized in the table. Only in experiment 1 was the stalk deliberately divided; in the remaining five, the intended procedure was a needle puncture of the base of the brain in the region of the tuber cinereum. Autopsy showed,

*Six Cases of Experimental Polyuria Lasting Four Months or More*

Experiment	Author	Animal	Operation Intended	Result	Microscopic Observations
1	Crowe, Cushing and Homans: Bull. Johns Hopkins Hosp. 21: 127, 1910	Dog 34	Stalk separation; partial removal anterior lobe	Polyuria present when killed at sixth month	Gland reunited to base of brain; fragment of anterior lobe present
2	Camus and Roussy: Presse méd. 22: 517, 1914	Mous-tachu	Puncture of tuber cinereum	Polyuria present when killed at seventh month	Stalk divided ("pas de tige") hypophysis atrophic
3	Camus, Roussy and LeGrand: Compt. rend. Soc. de biol. SG: 1070, 1922	Dog 107	Puncture of tuber cinereum	Polyuria for 5 months; present when killed?	"Hypophysis intact"; scar in base of brain
4	Camus, Roussy and LeGrand: Compt. rend. Soc. de biol. SG: 1070, 1922	Dog 108	Puncture of tuber cinereum	Polyuria for 6 months; present when killed?	"Hypophysis intact"; scar in base of brain
5	Camus, Roussy and LeGrand: Compt. rend. Soc. de biol. SG: 1070, 1922	Dog 1856	Puncture of tuber cinereum	Polyuria for 13 months; present when killed?	"The hypophysis was traversed and completely destroyed"; scar in base of brain
6	Bailey and Brémér: Arch. Int. Med. 28: 773, 1921	Dog 10	Puncture of tuber cinereum	Polyuria present when killed at fourth month	Posterior lobe detached from infundibulum; scar in base of brain

however, that the stalk was completely divided in experiment 2 ("pas de tige"); that the hypophysis was "traversed and completely destroyed" in experiment 5, and that the stalk was at least partly divided in experiment 6 ("The posterior lobe had been detached from the infundibulum . . ."). In experiments 3 and 4, the data are even more scanty than those in experiments 2 and 5. It is stated that the hypophysis was intact, but nothing is said about the condition of the stalk. Camus and Roussy were interested in the small needle scars in the base of the brain, and not in the pituitary gland. They ignored the stalk division in experiment 2, and the so-called complete destruction of the hypophysis in experiment 5, and attributed the polyuria in these animals to the microscopic lesions in the base of the brain.

When one considers the clinical results of these six experiments, it is found that polyuria was still present when three of the animals were

killed (experiment 1, six months; experiment 2, seven months; experiment 6, four months). In Camus and Roussy's experiments 3, 4 and 5, the protocols do not state whether or not the polyuria had terminated when the animals were killed. As experiments 3 and 4 have insufficient pathologic and clinical data, they are of little value in this analysis. Though the clinical data are also insufficient in experiment 5, the polyuria must have lasted nearly thirteen months, and the pathologic report is more complete. If experiments 3 and 4 are eliminated, four animals showed a polyuria lasting from four to thirteen months. In experiment 1, the stalk was divided, and serial sections showed that the gland had reunited to the base of the brain, that cells of the pars intermedia had invaded the pars nervosa and that fragments of the anterior lobe were present; whether or not the stalk division separated all cells of the pars tuberalis from the base of the brain is not stated. In experiment 2, the stalk was divided and the gland was atrophic; in experiment 5, the gland was "traversed and completely destroyed." The protocols of these two observations do not mention cells of the pars tuberalis. Finally, in experiment 6, the authors were interested in the needle puncture of the base of the brain, but the protocol and the accompanying sketch show clearly that the posterior portion of the stalk was cut, and leave one in doubt whether the anterior portion of the stalk was also divided. To summarize, of the four experiments in the literature which resulted in a polyuria lasting four months or more, and which give sufficient microscopic data, two had complete divisions of the stalk, one had partial (perhaps complete) stalk division and one had "complete destruction" of the hypophysis. Regarding the permanency of the polyurias produced by the experiments, the results in experiments 1, 2 and 5 may fairly be looked on as permanent, and in experiment 6 as certainly doubtful in view of the results in dogs 7 and 4, in which the polyuria terminated in the sixteenth and twenty-first week. There is little in this analysis to support the contention of Camus and Roussy that polyuria is due to lesions of the hypothalamus. Except for their dogs 107 and 108, in which the condition of the stalk is not mentioned, all of the intended punctures of the base of the brain which resulted in a polyuria lasting four months or more showed complete or partial division of the stalk. It is true that any operative damage to the upper portion of the stalk will also damage the tuber cinereum. But a pure lesion of the tuber cinereum or nearby base of the brain has never given a polyuria of four months' duration, again excepting Camus and Roussy's dogs 107 and 108, in which this may have been true. A large number of "piques" have resulted in polyurias lasting a few days or weeks, which mean nothing. Such experiments can just as logically be interpreted as meaning temporary interference with the secretions of pars intermedia products into the ventricle.

The experiments reported in this paper throw some light on the question at issue. In the series of five animals, of which dog 7 is a typical example, cells of the pars tuberalis were left attached to the base of the brain. The nerve cells of the nearby hypothalamus were not studied, but they undoubtedly would have shown the slight changes which Camus and Roussy stressed. These experiments might, and probably would, be interpreted by the proponents of the neurogenic theory of diabetes insipidus as confirmatory. On the contrary, those who believe that polyuria is due to suppression of the secretion of pars intermedia and pars tuberalis could interpret these experiments as meaning that the division of the stalk eliminated all the secretion of the pars intermedia permanently; that the trauma suppressed the secretion of the pars tuberalis for a varying number of weeks, and that the polyuria terminated because of proliferation of the cells of the pars tuberalis left above the incision. The size of these nests of cells, as shown at *d* and *e* in figure 2, undoubtedly supports this theory. It is granted that these five experiments may be interpreted differently, but they bring out one fact which seems of great importance; that is, the constant presence of a varying number of eosinophilic cells among the cells of the pars tuberalis left attached to the base of the brain. Such cells are never found in the pars tuberalis of normal dogs. Why they are always present in these experiments is not clear, but their presence is strong evidence that the frequent tendency to ignore the pars tuberalis as functionally inert is not justified. In the confused interpretations of pituitary physiology, one fact which is uncontested is that these eosinophilic cells of the pars anterior are always present in markedly increased numbers in cases of active acromegaly. The observation of similar cells, often in considerable numbers, among the cells of the pars tuberalis indicates that the pars tuberalis cannot be dismissed as of no functional importance.

The most important observation is the only one in which all the cells of the pars tuberalis were detached from the base of the brain. If diabetes insipidus is caused by injury of nerve centers in the hypothalamus, the extensive destruction of the floor of the third ventricle in dog 4 should have given a permanent polyuria. None of the areas described by Camus and Roussy escaped. The cessation of the polyuria in this animal would seem to eliminate the neurogenic theory of diabetes insipidus. On the other hand, why did the polyuria cease if it was due to suppression of secretion of the pars tuberalis and the pars intermedia? The reattachment of the pars intermedia to the uninjured base of the brain, with invasion down to the ependymal cells, gives a logical answer. The histologic picture of this area does not show any obstruction to the secretion of the pars intermedia products into the

ventricle. It is of interest that there were again eosinophilic cells among these cells of the pars intermedia.

After the failure of these experiments to produce a permanent polyuria, a new approach was made to the problem, suggested by the transplantation experiments of Crowe, Cushing and Homans.<sup>5</sup> The cessation of polyuria in dog 4 was interpreted as due to reattachment of the pars intermedia to the base of the brain, and an attempt was made to avoid this by removing the entire gland, including the pars tuberalis, and transplanting fragments of the pars anterior, the pars intermedia and the pars tuberalis to different points in the cerebral cortex. If a polyuria developed and ceased, it was planned to remove the transplants, one at a time, and watch the effect on the urinary output. The experiments were a total failure, because none of the six animals lived.

#### SUMMARY AND CONCLUSIONS

1. Experimental diabetes insipidus, lasting a few days or weeks, may be produced by a variety of procedures, and conclusions cannot be drawn from such experiments.

2. There are only four sufficiently reported experimental observations of polyuria lasting over four months. All showed partial or complete division of the pituitary stalk.

3. With the exception of Handelsmann and Horsley, investigators have ignored the possible physiologic importance of the pars tuberalis cells on the base of the brain.

4. Five divisions of the stalk, here reported, failed to detach all the cells of the pars tuberalis, and only one succeeded. The resulting polyurias terminated in from four to twenty-one weeks. Serial sections in the five cases showed nests of apparently active cells of the pars tuberalis above the scar, and among them varying numbers of eosinophilic cells typical of the pars anterior. In the one technically successful experiment, the gland had reunited to the undamaged portion of the base of the brain, and cells of the pars intermedia had invaded down to the ependyma.

5. These experiments, and an analysis of previously recorded lasting polyurias, do not support the neurogenic theory of Camus and Roussy, but strongly suggest that diabetes insipidus is due to suppression of the secretion of the pars intermedia and the pars tuberalis.

# THE SIGNIFICANCE OF A DILATED PUPIL ON THE HOMOLATERAL HEMIPLEGIC SIDE IN CASES OF INTRACRANIAL HEMORRHAGE FOLLOWING HEAD INJURIES

REPORT OF SEVEN CASES

CARL WHEELER RAND

There are few experiences more humiliating than to overlook a subdural clot when operating for intracranial hemorrhage in traumatic cases. To be sure, in the majority of instances the surgeon has sufficient signs and symptoms on which he can rely to make a correct localizing diagnosis; but occasionally cases present themselves which are baffling from the standpoint of localization. It has usually been my experience to find a hemorrhage on the side of the dilated pupil regardless of other neurologic aspects, and it is my purpose to report the following cases to emphasize the importance of "following the pupil."

It has been taught that the pupils go through two reactive phases in cases of damage to the brain or hemorrhage. The first or irritative phase is said to cause constriction of the pupil which later may change to dilatation if the cortical pressure becomes high enough on the side in question. The reaction of the pupil depends on the correlated interaction of the cervical sympathetics and the oculomotor nerve by way of the ciliary ganglion. It seems futile to try to evaluate the degree in which these antagonists counterbalance each other in considering inequality of the pupils in cases of injury to the head. On the surface it would seem that first stimulation and later impairment of the oculomotor nerve must play the greatest part. In speaking of extradural hemorrhage, Cushing<sup>1</sup> stated that "pupillary symptoms, particularly inequalities, are common in this as in other forms of unilateral intracranial hemorrhage. The pressure of the clot against the hemisphere is said to cause an early narrowing of the pupil on the same side and later on a dilatation. This dilatation in the late stages may affect both pupils, but even then the pupil on the side of the lesion remains wider." Some observers are prone to place considerable importance on the presence of a dilated pupil, while others place little reliance on it as a localizing sign in cases of suspected intracranial hemorrhage. In discussing this point, an eminent neurologist once remarked to me that a dilated pupil "was a straw showing which way the wind was blowing." It has seemed to me that his impression, gained by many years of clinical observation, was well founded.

---

1. Cushing, Harvey: *Surgery of the Head*, in Keen: *Surgery*, Philadelphia. W. B. Saunders Company, vol. III, 1908, pp. 17-276.

Holman and Scott<sup>2</sup> have recently stressed the "significance of unilateral dilatation and fixation of the pupil in severe head injuries." They discussed the difficulties of evaluating localizing signs in unconscious patients, in general making a plea for paying more attention to the state of the pupil as a guide in diagnosis. A number of cases are given among which is one in which there was dilatation and fixation of the right pupil in the presence of a right-sided weakness. A left decompression was done because of the right hemiparesis, disregarding the dilated right pupil. Twenty-four hours later the patient died and an autopsy showed "an extensive right sided subdural

Fig. 1.—Specimen of brain in Dr. Holman's case. Extensive hemorrhage and cortical injury in the right frontotemporal region. The bulging area of the left temporal lobe is the seat of a decompression opening. The patient had a right-sided hemiparesis and a dilated pupil on the right side.

hemorrhage over the frontal and temporal regions, with a long laceration of the cortex of the temporal lobe." About an hour and a half before death the left pupil became widely dilated and fixed, and remained so until the end. Their case is illustrated by a photograph of the brain which Dr. Holman has permitted me to reproduce (fig. 1). Their experiences "indicate that unilateral dilatation and fixation of

2. Holman, E., and Scott, W. M. J.: Significance of Unilateral Dilatation and Fixation of Pupil in Severe Skull Injuries, *J. A. M. A.* 84:1329 (May 2) 1925.

the pupil almost invariably occur on the side of the lesion at some time in the course of the progressively increasing cerebral compression from hemorrhage, and serve as a valuable aid in determining the side on which the decompression should be performed. In certain instances the large dilated pupil has been the only diagnostic sign of localization, and . . . *has proved to be of even greater localizing significance than bleeding from the opposite ear, or even a hemiparesis of the same side.*"

In a supplementary note, reference is made to a discussion of the subject by William Macewen<sup>3</sup> in 1887, which it would seem is enlightening. He stated:

One pupil dilated and fixed, the other normal. Many instances have been observed of dilatation and fixity of one pupil, while its fellow, perhaps with the exception of a little sluggishness of movement, remained normal. These were all cases of fracture of the middle fossa of the skull, and in comparatively few of them was the diagnosis verified by postmortem examination, though little doubt could exist as to the lesion when accompanied as they were by the usual phenomena of hemorrhage from the ear, followed by discharge of cerebrospinal fluid, ptosis, occasionally external strabismus, facial hemiplegia and paralysis of members. In such the patient was generally insensible at the outset, when both pupils were dilated and fixed. As the patient recovered consciousness, *one pupil became normal while the other remained dilated and fixed, this being on the side of the lesion.* In some of these the visual power on the same side as the dilated pupil was in abeyance; in others, it was imperfect, and in a few it was almost normal. The pressure exercised by the blood clot must have been sufficiently great to place in abeyance the function of the greater part of the affected hemisphere, as evidenced by the complete paralysis of the opposite member, the interference with vision, and the evident effect upon the third nerve. In those cases in which postmortem examinations were obtained, the basal fracture was continued into or toward the vertex, and the clot in most instances occupied the whole of the middle fossa from the petrous portion of the temporal to the vertex, the convolutions, especially the ascending, being considerably compressed. The opposite hemisphere was in almost a normal condition. In those that recovered, the dilatation gave way slowly, and was followed by a degree of contraction, along with sluggishness of movement which ultimately passed off, though in one case it still remained small and sluggish at the termination of the fifth month from the date of the accident. These changes were evidently determined by the gradual absorption of the blood clot. It is more than likely that in most of them the third, as well as the seventh nerve was paralyzed, and in one or two instances the fifth, in addition, as indicated by the loss of sensation on the affected side. Occasionally the second was interfered with. Hearing was generally much affected, if not absolutely in abeyance on the affected side, during the early months, mechanical obstruction by blood clot producing loss of hearing as well as interference with the nerve.

The significance of pupillary changes and inequalities following injuries of the head has been the subject of comment for many years.

---

3. Macewen, William: The Pupil in Its Semeiological Aspects, Am. J. M. Sc. 94:123, 1887.

Few authors have given as precise a description as that of Macewen just quoted. Vance<sup>4</sup> summarized his experience in which autopsy was performed as follows:

In several instances the pupils were unequal, one was dilated, while the other was contracted, and this sign seemed to point to a lesion definitely located on one side of the cranial cavity. In seven fatal cases in which there was a subsequent necropsy, the right pupil was observed to be much larger than the left. Five of these showed an epidural hemorrhage on the right, one a subdural hemorrhage on the right and one an epidural hemorrhage on the left. The cause of the inequality was not easy to determine, but the difference in the size of the pupils depended, apparently, on the unilateral nature of the intracranial condition.

He mentioned the fact that "one patient for some reason showed a paralysis of the arm on the same side as the epidural clot." Unfortunately the condition of the pupils was not mentioned in this case.

Carter,<sup>5</sup> reviewing a large series of fractures of the skull (223), found 48 cases in which the pupil was dilated on the side of the lesion, 20 cases in which it was dilated on the side opposite the lesion, and 155 in which there was no pupillary change. There was a mortality rate of 52 per cent in cases in which the pupil was dilated on the side of the lesion and 95 per cent when it was dilated on the side opposite the lesion. He observed that "when a pupil which was large on admission comes down to normal size, the prognosis is apt to be favorable; but when a pupil which was equal to its mate on admission later becomes dilated, we feel that the intracranial damage is progressing and become suspicious of an extra or intradural hemorrhage." He does not mention cases of a dilated pupil on the same side as a hemiparesis.

In reviewing 755 cases of injuries to the brain at the San Francisco Emergency Hospitals, Butler<sup>6</sup> stated:

The most valuable localizing sign as to the side of the compression and the degree of compression, in my experience, has been the condition of the pupils. The pupil on the side of the beginning compression at first reacts very sluggishly, often showing a hippus. As the compression increases this pupil slowly contracts, reacting at first, later pin point and fixed, finally dilating slowly, followed by the same course of events in the other pupil.

Menninger<sup>7</sup> discussed the condition of the pupils in various states of coma, and commented on cases of fracture of the skull. Anisocoria

occurred eight times in twenty-five cases of proved fracture, the pupil on the side of the trauma being dilated in every case at some period following the injury. In thirty cases of probable fracture the pupils were unequal thirteen times, the dilated pupil being on the same side as the trauma in nine instances and contrecoup in four. He felt that "it is necessary in these cases to watch the pupils closely to detect anisocoria, since it is often of a transient nature, being present in some observed cases only a few minutes." He stressed the unilateral dilatation of a pupil as an aid in locating the lesion for surgical intervention.

#### REPORT OF CASES

*CASE 1.—Dilatation of the left pupil in conjunction with the appearance of a left hemiplegia, five days after a severe injury to the head. Bilateral decompression. Subdural hemorrhage found on the left side. Death.*

D. S., a woman, aged 46, white, married, was admitted to the neurosurgical service of the Los Angeles General Hospital on Feb. 11, 1926. About 11 p. m. on February 10, while standing in the street, she was struck by an automobile and knocked down. She was unconscious, but soon aroused from coma and was admitted to the hospital the next day in an irrational condition. She then became conscious but was confused at times until February 15, when she again went into coma. On admission to the hospital, there was a large hematoma over the right temple, and the right eye was swollen shut. The pupils were equal, the fundi normal and there was no evidence of paralysis of any extremity. All superficial and deep reflexes were hyperactive and equal. There were no abnormal reflexes of the Babinski group and no ankle clonus, right or left. On the evening of February 16, five days after admission, her stupor deepened to coma. It was noted that there was *inequality of the pupils, the left being larger than the right*. It was noted also that there was a developing left-sided hemiplegia with a corresponding increase of the deep reflexes. The right knee reflex, however, seemed greater than the left. There was a double positive Babinski sign at this time. A roentgenogram of the skull taken on admission showed separation of the coronal suture at the vault. Two lumbar punctures, performed on February 15 and 16, showed a clear spinal fluid under greatly increased pressure. The Wassermann reaction of the blood was negative. It was evident that there was increasing intracranial pressure. The picture was confusing. The patient had a large hematoma on the right side of the head, with a left hemiplegia developing five days after injury. The left pupil was dilated at this time, being considerably greater than the right.

A bilateral subtemporal decompression was done by my associate, Dr. G. H. Patterson, on February 16. On the right side, which was opened first, the brain was found to be swollen and wet, but hemorrhage was not encountered. The left side was then opened and a subdural currant-jelly clot was found. This clot measured approximately 10 by 10 cm. in diameter and was about 1 cm. thick. It was removed, and both wounds drained. Following the operation, the patient did badly in spite of free drainage of cerebrospinal fluid and intravenous injections of hypertonic dextrose. She died at 4 a. m. on February 18, with typical signs of hyperthermia.

The coroner's autopsy report on February 18 was as follows: "The scalp was contused and lacerated on the right side of the head, about 2 inches above the angle of the right eye and 1 inch external to the latter. The contused area

was about 1½ inches in diameter and round, in the center there was an area about 1 inch in diameter where the skin was perforated. On reflecting back the scalp a fracture was found running from this area across the top of the skull to within 1½ inches of the left ear. The fracture gaped sufficiently to easily admit the blade of the knife and was about 8 inches long. The right eye was markedly discolored as was the bridge of the nose. There was a lacerated contusion on the outer side of the right ankle joint. A decompression operation had been performed on both sides of the head. There were no visible injuries of the body. The cause of death was fracture of the skull."

In this instance the coroner did not find a subdural hemorrhage as it had been removed at operation. The hemorrhage was on the left side, the same side as the dilated pupil and the same side as the hemiplegic symptoms. Mention was not made of the general condition of the brain by the coroner, but at operation it was observed to be swollen and wet. Whether or not there were deep contusions of the right cerebral hemisphere is not told, and one is left in the dark as to the cause of the left hemiplegia.

*CASE 2.—Dilatation of the left pupil with left hemiparesis five hours after severe injury to the head. Right-sided decompression, no hemorrhage, but bruised swollen brain. Death. Coroner reported large subdural hemorrhage covering most of the left cerebral hemisphere.*

L. C., a man, aged 35, white, married, a motorcycle officer, was seen on the night of May 27, 1926, in consultation with Dr. N. C. Paine of Glendale, Calif. About 8 o'clock that evening he was thrown from his motorcycle and rendered immediately unconscious. He was examined about five hours later.

At the time of examination he was found to be in deep coma. There were abrasions about the right cheek and temple, and a large hematoma was present under the right temporal muscle. There was no bleeding from the ears. The pupils were fixed, and *unequal, the left being much larger than the right*. The fundus on the left showed the disk to be hazy, but the vessels were not particularly engorged and there was no measurable elevation. A few fine hemorrhages were seen. One was unable to examine the cranial nerves serially. Shortly after the injury it was noted that the patient moved the left arm and leg less than the right. When examined all extremities were practically flaccid. At times he would go into extensor rigidities. A positive Babinski sign was obtained on the right at times, but it was not constant. There was no ankle clonus on either side at any time, nor could superficial or deep reflexes be obtained anywhere. A roentgenogram of the skull showed a fracture on the right side running down toward the zygoma.

I quote from the discussion written down before the operation. "It was apparent that the patient had received a very serious head injury, concussion and contusion of the brain and a skull fracture on the right side. The large pupil on the left and the positive Babinski on the right would suggest pathology in the left cerebral hemisphere. The blow, however, was received on the right side where a large hematoma was present, the skull fracture was on the right, and there was a history of greater weakness of the left upper and lower extremities soon after the accident."

In spite of the patient's critical condition, it was decided to perform a right subtemporal decompression. A large hematoma was found under the temporal muscle, which was lacerated and torn. A linear fracture of the skull was

encountered low down in the temporal bone extending down toward the base of the middle fossa. The dura was ecchymotic and under great tension. When this membrane was opened the brain bulged dangerously, but the cortex did not rupture. The brain was badly bruised and greatly discolored, almost purplish. No extradural or subdural hemorrhage was found. The wound was drained before closure. The patient's condition became worse during the following twelve hours when he died. Before death he developed hyperthermia, the last temperature being  $105 + F.$ , the pulse rate,  $160 +$ , and the respirations above 40 per minute.

The coroner examined the brain which was found to be greatly bruised and swollen. The greatest damage was in the right cerebral hemisphere. *A large subdural hemorrhage was found covering most of the left cerebral hemisphere.* The point of bleeding was not established. The coronal suture was said to show separation and a linear fracture ran across the right temporal bone, traversing the base of the skull.

In this instance there was enough damage to the right hemisphere to account for the signs of the left hemiparesis observed soon after the injury. The hemorrhage of the left subdural space probably did not manifest itself at first, and later the patient's condition would not permit a localizing neurologic diagnosis. However, enough importance was not given to the dilated left pupil which was present from the first.

*CASE 3.—Dilatation of the right pupil with right hemiparesis within a few hours following injury to the head. Bilateral decompression two days later. Subdural hemorrhage found on the right side. Death.*

J. G., a woman, aged 32, Mexican, married, was admitted to the Los Angeles General Hospital on Oct. 24, 1926. She was in an automobile collision earlier in the day; was thrown out and brought to the hospital unconscious. There was a contusion and ragged laceration of the scalp in the left parietal region. There was bleeding from the left ear. The blood pressure was 98 systolic and 60 diastolic, the pulse rate, 80. A roentgenogram of the skull showed a linear fracture beginning in the midportion of the left parietal extending downward and forward into the temporal bone, and ending close to the external auditory meatus.

From the first slight paralysis of the right arm and leg was noted, and the right pupil was larger than the left. On the day following admission the patient moved the right arm and leg slightly, but moved the left arm and leg freely. It was noted that the hemiparesis of the right side had increased. The deep reflexes of the right side also were more active than those of the left. There was a positive Babinski sign on the right; the sign was negative on the left. *The right pupil remained larger than the left.* By the next day, the stupor had deepened. The pulse rate was 60; the blood pressure, 100 systolic and 60 diastolic and the temperature,  $100 F.$  The Wassermann reaction of the blood was negative. The spinal fluid was bloody.

The following picture was encountered: external bruising of the left side of the head, bleeding from the left ear, right-sided hemiplegia, dilated right pupil and fracture of the skull on the left side as shown in the roentgenogram. It was thought there was a subdural hemorrhage on the left side, but provision was made to explore the right side also if hemorrhage was not found on the left.

On October 26, my associate, Dr. G. H. Patterson, did bilateral subtemporal decompressions. The left side was done first, and a very small extradural clot was found, but subdural hemorrhage was not encountered. The brain was swollen

and bruised. The right side was then explored where a large subdural clot was found. This was evacuated and drained. The bleeding vessel was not found. The patient did not do well postoperatively. On October 27, she ran a fast pulse (from 140 to 160) and a temperature from 103 to 104.4 F. She died about 6:25 p. m. on October 28.

The coroner's report follows: "We found an abraded contusion on the left side of the back in the lumbar region which was about 2 inches square. We opened the body, but no injury to the chest or abdominal organs was found. Two decompression operations had been performed on the head, one on each side above the ear. On opening the skull we found a diffuse meningeal subdural hemorrhage over the *right* hemisphere of the brain. The cause of death was traumatic cerebral meningeal hemorrhage."

In this instance the hemorrhage was found both at operation and at autopsy on the right side. The patient had a *right*-sided hemiplegia and a dilated pupil on the right side. It is probable that although the field seemed dry at the close of the operation after the removal of the clot, the bleeding continued and the clot reformed. It was this second clot which was found at autopsy. Unfortunately, a careful description of the brain itself was not given in the autopsy report. The little information that could be gained from the left-sided decompression showed that this hemisphere was bruised and swollen, possibly enough to account for the right hemiplegia.

*CASE 4.—Dilatation of the left pupil with left hemiplegia following injury to the head. Right-sided decompression ten days later. No clot found. Death three days later. Autopsy revealed large epidural clot on the left side.*

G. N., aged 14, white, a school boy, was first seen in consultation with Dr. F. D. Fairchild at the Methodist Hospital on Feb. 28, 1927.

He was injured on February 26, while riding his bicycle hanging on to the back of a truck "for a lift." When the truck went over an irregularity in the road he was thrown off, striking his head and being immediately rendered unconscious.

At the time of examination two days later he had not regained consciousness. There was evidence of bleeding from the right ear. Both eyes were ecchymotic and swollen. The pupils were small, possibly the left was a little larger than the right. They both reacted to light. The fundi showed congestion of the veins, but there was no elevation. The boy moved his right arm and leg freely, but made little effort to move the left. The deep reflexes on the left were increased as compared with the right. There was a double positive Babinski sign, but no ankle clonus on either side. The left collar bone was fractured. The temperature was 102 F.; the pulse rate, 160 and respirations, 20. A roentgenogram of the skull was inconclusive for fracture.

The lad was observed for about a week. During this time his pulse steadied down to about 100, and his temperature varied from normal to 102 F. *The left pupil gradually became larger than the right.* He continued to use the right arm and leg freely, but the left side became practically useless. All deep reflexes became greatly diminished and at times could not be obtained. The Babinski signs disappeared. An outward deviation of the right eye developed.

It was thought advisable to explore the right side, and, on March 7, a right subtemporal decompression was carried out. The dura appeared normal and was

not under increased tension. No extradural or subdural hemorrhage was found. The brain was bruised and ecchymotic, but there was little increased pressure. The wound was closed without drainage.

For the next three days after the operation the patient's condition remained precarious. The question of opening the left side to search for a possible hemorrhage was discussed, but was not insisted on. The patient died on March 10, thirteen days after his injury.

Fig. 2.—Base of the skull taken at autopsy in case 4. A massive extradural clot is seen on the left side. This patient had a dilated left pupil and a left hemiplegia. A small hemorrhage can be seen in the region of the vermis. A skull defect on the right side shows site of right subtemporal decompression.

The coroner made a postmortem examination which I was privileged to witness. When the skull cap was removed an enormous extradural hemorrhage was found on the left side. Figure 2 is a photograph of the base of the skull taken at the time, showing the extent of the clot. It will be noted that there was a small hemorrhage in the posterior fossa just above the vermis of the cerebellum. No subdural clot was found on either side. The brain appeared swollen and bruised, but nowhere were there extensive lacerations of the cerebral substance, and no large isolated clots were found in the subcortical areas.

In this instance the left pupil was but little larger than the right during the first few days following the accident. As time went on, however, it gradually became more dilated and during the last three days of life was twice as large as the right. Permission for a bilateral decompression should have been insisted on.

*CASE 5.—Dilatation of the left pupil and development of left hemiplegia a day following injury to the head while boxing. Bilateral decompression. Subdural hemorrhage found on the left side. Recovery.*

O. M., a man, aged 20, white, bank clerk, single, was first seen in consultation with Dr. O. F. Mueller at the Hollywood Hospital on Oct. 31, 1927. About 4:30 p. m. on October 30, he was boxing with a friend. He received a sound blow on the left side of the head, and was knocked to the mat. He was dazed for a second or two, but probably was not knocked out. At 7 p. m. he had considerable headache, felt squeamish and did not eat his dinner. The next morning his headache was more severe and he vomited. He became drowsy and about 11 a. m. become unconscious. Soon after this a left hemiplegia appeared. A lumbar puncture showed increased pressure. The first spurt of the spinal fluid was clear, but then became bloody. The second test tube of fluid was very bloody.

He was seen about 5 o'clock on the same afternoon. At this time he could be roused enough to talk, but was dazed and disorientated. There was no bleeding from either ear. There was moderate swelling about the left temple where the blow had fallen. The left pupil was about twice as large as the right. Both reacted well to light. There was moderate ptosis of the left upper lid. The eye-grounds were normal. There was definite left hemiplegia. He would move the right arm and leg readily. The left leg was moderately weak, the arm very weak, and there was paralysis of the left side of the face of the central type. The abdominal and epigastric reflexes as well as all deep reflexes of both upper and lower extremities were obtained and were exaggerated on both sides. No ankle clonus was present. The pulse rate was 80; the temperature, normal; the blood pressure, 140 systolic and 90 diastolic. There were 14,800 white blood cells.

The comment made before operation is quoted: "It is felt the boy has a subdural hemorrhage. The question arises whether this hemorrhage is on the right side as would be indicated by his left hemiplegia, or on the left side as would be indicated by the enlarged pupil. The latter is favored, although the operator does not feel that he can neglect exploring the right side as well."

Bilateral subtemporal decompressions were carried out. When the right side was opened, the dura appeared normal, with moderately increased tension. The brain was of the wet, sweaty type and there was a considerable excess of clear cerebrospinal fluid. A brain-spoon was passed in various directions, but hemorrhage was not found. The wound was drained and closed. The left side was then similarly explored. The dura was purplish and mottled, but the tension was subnormal. In fact, the dura sagged, probably due to relief of pressure on the right side. When the dura was opened a currant-jelly clot was encountered which measured 1 cm. in thickness and 10 by 10 cm. in diameter. It was washed out. The wound was then drained and closed. The point of hemorrhage was not found.

The boy's convalescence was satisfactory. A weakness of the left external rectus muscle was noted the day following operation and persisted for several weeks. It gradually disappeared, the ocular movements being normal by Feb. 1, 1928. The hemiplegia cleared up, although there was some weakness and awkwardness of the left hand for six months after the injury.

CASE 6.—*Right hemiplegia following fall in a woman, aged 62. Hemiplegia cleared up in a few days. Gradual development of stupor, with recurrence of right hemiplegia thirteen days later. Dilatation of right pupil fifteen days after injury. Death eighteen days after injury. Large subdural clot on the right side revealed at autopsy.*

F. D. P., a woman, aged 62, was first seen in consultation with Dr. F. N. Chessman at the Good Samaritan Hospital on July 6, 1928. About 7:15 a. m. that morning her maid found her unconscious in her dressing room. She was in deep coma, and there were blood clots on the floor from a small lacerated wound of the scalp in the left occipital region. There was a moderately large bump on the left side of the forehead. The entire right side was rigid; she was cyanotic and her breathing was stertorous.

She was seen a few hours later at the hospital. Examination revealed a white haired woman about 5 feet, 3 inches tall (160 cm.), weighing 165 pounds (74.8 Kg.). Small contusions of the left frontal and the left occipital regions were noted. Her breathing was easy and her color good. She responded to stimulation by moaning and moving a little. The pupils were small, equal and responded sluggishly to light. The fundi did not show any abnormal changes. There was weakness of the right lower side of the face, and the right arm was flexed and spastic. There was some spasticity of the right leg. Nothing abnormal was made out in the heart, lungs or abdomen save a well healed laparotomy scar in the latter. The superficial reflexes were not obtained. The biceps and triceps jerks were quicker on the right than on the left. All other deep reflexes of both upper and lower extremities were present, normal and equal. There was no Babinski sign on either side and ankle clonus was not present.

The urine was normal, save for a faint trace of albumin; the hemoglobin was 86 per cent; red blood cells, 4,928,000; color index, 0.87; white blood cells, 10,500; differential: polymorphonuclear leukocytes, 82 per cent; lymphocytes, 14 per cent; transitionals, 4 per cent. The temperature was 98.6 F.; the pulse rate, 96; respirations, 16 per minute. The blood pressure was 190 systolic and 100 diastolic. Roentgenograms of the skull did not show any evidence of fracture. It was my impression that she had suffered a stroke of apoplexy, the hemorrhage being subcortical on the left side. The bruises on her head were considered of secondary importance.

During the next few days her condition improved materially. She became conscious, was well orientated and was anxious to know if she could take a trip to Alaska as she had planned. The weakness on the right side cleared up so that it was hardly noticeable. It was commented on that it seemed strange that there was no defect in speech, as would have been likely in a left-sided cerebral hemorrhage. A positive Babinski sign was found on the right side at times. The blood pressure dropped to 150 systolic and 80 diastolic. Eight days after the onset she complained of some headache. Twelve days after the onset the headache became severe and she showed a tendency to drowsiness.

On July 19, thirteen days after the onset, her headache became more severe and she was stuporous at times. It was noted that the right arm and leg were again becoming paretic, the right arm more so than the leg. The pupils were equal and reacted to light and distance. The fundi showed some congestion of the vessels, but the disk margins remained clearcut. The deep reflexes on the right were greater than on the left; there was a positive Babinski sign on the right and a negative sign on the left. The blood pressure rose to 160 systolic and 90 diastolic, but the pulse remained about 80 and steady.

On the morning of July 21, she was in deep coma with stertorous breathing and moisture throughout the chest. On this date *it was noted for the first time that the right pupil was greater than the left*; both were static. The fundi showed over-filling of the veins, but were otherwise normal. The deep reflexes of the arms were active and equal. No deep reflexes of the lower extremities could be obtained, but there was a double positive Babinski sign. A lumbar puncture at this date showed a clear, slightly yellowish spinal fluid under 320 mm. of pressure. It contained one cell, a slight increase in globulin content and a negative Wassermann reaction.

The question of exploration for a subdural hemorrhage was discussed and was not considered feasible. The patient lingered for three more days and died

Fig. 3.—Brain in case 6, showing remains of a large subdural clot on the right side. This patient had a right hemiplegia and dilated right pupil shortly before death. A left-sided cerebral apoplexy had been diagnosed.

on the morning of July 24, with a terminal temperature of 107.6 F.; pulse rate 150 and respirations of 60 per minute. I was not satisfied that the condition was a cerebral hemorrhage of apoplectic origin, although I did not sense the significance of the dilated right pupil which was present for three days before her death.

Autopsy of the brain was performed by Drs. Hammack and Maner on July 2. Their report follows:

"On removing the calvarium the dura over the right hemisphere is bulging and dark blue. That over the left hemisphere appears normal. There is an extensive subdural hemorrhage completely enveloping the whole superior aspect of the right cerebral hemisphere (fig. 3). It is approximately 1 cm. thick. The

center of this is soft and consists of fluid blood and dark red clots while the outer portion is more firm greyish red, stringy and is adherent to the inner surface of the dura. The pia of the hemisphere is present and is uniformly thin and blood stained. The right hemisphere is compressed and over the upper portion of the parietal and frontal lobes the surface level is approximately 1 cm. beneath that of the left hemisphere. The convolutions are smaller and more prominent than the corresponding ones on the left side. The hemorrhage is limited to the anterior and middle fossae of the skull, the falx cerebri and the tentorium cerebelli acting as barriers, there being no hemorrhage whatever in the posterior fossa surrounding the cerebellum, nor any hemorrhage over the left hemisphere.

"The ventricles are apparently of normal size but the right is flattened. The medial surface of the right hemisphere bulges to the left and there is a pressure indentation on the medial surface of the left hemisphere. There is no hemorrhage into the ventricles or the basal ganglia. The vessels over the cortex on the right side are all thin walled and distended. No points of rupture can be demonstrated. The basilar artery is tortuous and 's' shaped and the walls are thickened and somewhat beaded. The vertebral vessels are thickened and arteromatous. The left middle cerebral artery is moderately thickened and atheromatous and the lumen is larger than the corresponding vessel on the right. The dura itself does not appear to be thickened. The hemorrhage appears to be attached to it by means of a thin reddish brown membrane which scrapes away easily. The skull is very thick and dense but no fractures can be demonstrated.

"Cause of death: Extensive subdural hemorrhage involving the whole of the right cerebral hemisphere."

*CASE 7.—Dilatation of the left pupil and occurrence of left hemiplegia six hours following injury. Disappearance of these symptoms the next day, to return three days later. Death eight days after injury. Autopsy revealed large subdural hemorrhage over the left parietal lobe.*

Dr. William Edler of Pasadena, Calif., gave me notes on a similar case which came under his observation about two years ago.

T. R., a woman, aged 53, was riding in an automobile on June 16, 1926. A rear end collision with another automobile occurred. Her head was forcibly jerked back, and she struck the back of it against the upholstering and framework of the car. She apparently did not suffer any ill effects, and drove home. An hour or so later, she had some headache and nausea and called her physician, Dr. Luckey. She had formerly been under his care for hypertension, and he attributed her complaint to this condition. That afternoon when the patient complained of some weakness in her left arm, he was called again.

A neurologic examination at this time disclosed complete paralysis of the third nerve with accompanying mydriasis on the left side. There was a spastic paralysis of the left arm and a semispastic paralysis of the left leg with pathologic toe phenomena on the left side. A spinal puncture showed a clear fluid under 20 mm. of pressure (mercury). The following day the whole syndrome had cleared up. The ocular movements were normal, and the patient had regained complete consciousness. Three days later, the whole picture recurred accompanied with deep coma. The spinal fluid was clear and drainage produced no effect. She died eight days after the accident. The postmortem examination done by the coroner showed a fracture through the petrous portion of the temporal bone. There was a large subdural hemorrhage over the left parietal cortex.

## SUMMARY

It is believed that hemorrhage is usually greatest on the side of the dilated pupil. In cases in which hemiplegia and the dilated pupil were homolateral, intracranial hemorrhage was found on the same side.

Apparently bitemporal decompressions are indicated in such cases, as either a dilated pupil on the homolateral side or a hemiplegia on the contralateral side are too important to disregard in looking for hemorrhage.

In some cases one is unable to assign any cause for the homolateral hemiplegia. In others, extensive damage to the opposite cerebral hemisphere has been found at autopsy. This may account for the contralateral hemiplegia.

Any mydriatic should be avoided in studying cases of injury to the head, as it may cover up a unilateral dilatation of the pupil. Morphine likewise should be avoided if possible, as it causes myosis and also is contraindicated from the standpoint of concealing signs of oncoming stupor.

# THE ART OF SURGERY \*

ELLIOTT C. CUTLER

Surgery began as a child of trauma. When our prehistoric ancestors fell from trees or their descendants stumbled at the mouth of a cave and broke their bones, there appeared the need of some form of treatment. Men injured in battles—in early days restricted to personal encounters, though now through what is called civilization involving whole nations—needed care. Splinting, bandaging and perhaps even the use of the tourniquet must have been the earliest developments. Later, with sharpened flint, blood was let, abscesses emptied, tissues scarified, and even skulls trephined. Gradually, experience demonstrated the best methods of care. By repeated application of this elementary knowledge, a certain degree of skill was developed, and the first teachers of surgery began to hand on their craftsmanship. Thus surgery began as an art. By an art is meant the skilful application of knowledge in effecting a desired result. It is a matter of craftsmanship as opposed to science. It is practice in comparison to study of the ascertained truths or facts. It connotes the use of the hands. Thus all surgeons are in a sense artists, just as musicians, sculptors, painters and architects are artists. And this matter of the proper use of the hands in the skilful performance of one's tasks is still the major problem in surgery. Science, which is the systematization of knowledge and its study, must be the surgeon's next-of-kin and his greatest aid in progress toward a fuller exploitation of the art, but for the art itself there remains and always will remain the supreme necessity for skilful handiwork. This in surgery is the basis of practice. And this technical skill is acquired by practicing precisely and beautifully the principles of surgery.

Surgery, today, in the minds of the laity is considered largely an art, a matter of handiwork. This attitude of mind is deeply rooted in the past, and nonprofessional people cannot evaluate the knowledge which perfects the art. Shortly after the time of Hippocrates when all branches of the healing art were happily unified, surgery came to be looked on largely as a menial task involving simple craftsmanship. The mediciner considered himself too much a scholar to humble himself with practical remedial measures such as bloodletting or the care of wounds and fractures. These procedures were relegated to the barbers who were among those who used their hands, and who moreover possessed cutting instruments. Thus in a sense, armamentarium played a part in the creation of the first medical specialty, surgery. But with this

---

\* From the Department of Surgery, the Western Reserve University School of Medicine and the Lakeside Hospital, Cleveland.

segregation of the practical manual remedial measures to the barbers, the mediciners lost a most important stimulus. They relegated to a great extent matters which required handiwork, and moreover matters frequently requiring immediate assistance. The imperative demands that result from trauma necessitate immediate therapy. In addition, the interior of the body may be exposed. Experience, obtained through the method of trial and survival, resulted in the slow accumulation of knowledge. Driven by urgent necessity to treat, the immediate matters gave rise to a practice, to an art that was slowly improving with the handing down to succeeding generations of the results of the practice of the art of its predecessor. Practice makes for perfection, and as the barbers practiced, so they learned, while their scholarly confrères were lost in fruitless speculation and scholastic subtleties. The mediciners became philosophers and turned away from experimentation and the study of the body. They were forced into that narrow conservatism and into that intellectual trap which considers historical knowledge as wisdom, and which inhibits observation and search for the truth. Thus medicine passed through the dark ages. The surgical members of the profession, though outcasts, used their hands and applied their art. Urgent necessity drove them to make a trial, and by trial valuable facts were accumulated. Gradually these barber-surgeons began to unravel the mysteries of the body, and their development culminated in the great figures of Paré and Hunter. The mediciners, withheld by tradition from close touch with the body, saw their despised colleagues bring to the profession of medicine observations of the greatest importance. As is always true, practice brought forth the art, and practice of the art begat science.

The matter of the art of surgery has indeed largely held predominance in the minds of surgeons themselves. This has been both fortunate and unfortunate: fortunate in that great attention to the practical performance of the task has resulted in great emphasis being placed on the skill and dexterity with which the operation may be performed; unfortunate in that it has given undesirable emphasis on manual dexterity alone. Human beings for the most part find satisfaction in using their hands. One has but to watch the baby, see the young child with his crayon and blackboard, study the boy with his knife or the avocations of "grown-ups." It is not unnatural, therefore, that the surgeon whose work must daily be accomplished with his hands should place the greatest emphasis on his manual ability. But skill in practice will not perfect the art unless at the same time all available knowledge be utilized to improve the methods of practice. In modern times, surgery practiced by the hands but without a knowledge of anatomy, physiology and bacteriology would not be tolerated. Thus the surgeon must keep abreast of the march of medical science, and in

fact, must play a rôle therein himself. He must not practice blindly, nor must he become so engrossed in the practice that he is deterred from the making and correlating of new observations which in turn will better his art. This danger of too great attention to the practice is common to all professions in which handicraft prevails. It has in surgery given rise to the suggestion that individual members of this specialty might well be designated as either surgeon or operator. Individuals in the latter group, because of the mass and attraction of the craft itself and though most skilful from the constant use of their hands, fail to make original observations or to see the principles and problems which daily pass their ken. But others who are called surgeons, such as Billroth, Thiersch, Halsted, and he in whose honor these papers are dedicated, found in the daily accomplishment of their task principles and problems of supreme importance for the betterment and development of the art. Such people have the great gifts of imagination and persistency. Moreover, they are more than craftsmen because whatever they do an inner spirit moves them to do beautifully. They recognize the value of details and realize that on the finesse with which such details are accomplished depends the final result.

Surgeons of this type approach their operations with trepidation, because they realize far better than their busy colleagues the risks and dangers of the operation. Etched on their sensitive souls is the ideal of healing per primam intentionem, and their observations have made clear the danger of loss of blood. Their imagination will picture the terrible possibilities of simple technical errors for which their intelligence has already demonstrated both the cause and the prophylaxis. They will visualize the hurriedly tied ligatures, which they know may suffice for hemostasis toward the end of a long operation with a falling blood pressure, "blowing off" later with the restoration of a normal blood pressure. They will worry about the difficulty of bringing ten sterile hands to the wound, about the proper toilet of the skin, the draping of the sterile linen, the assistant with coryza, the new scrub-nurse, the willing but stupid and overzealous orderly and the hundred important matters, all of which must reach perfection if the patient is to be completely protected. The greater the knowledge, the more the worry. Individuals of this type will not rest content to let assistants close their wounds; they will be driven by a sense of responsibility to see the job through, even to the dressing and finally to seeing that the unconscious patient is placed in the correct position in bed. All this concerns the art of surgery, the handiwork which willy-nilly must be the surgeon's task each day. It concerns things done with the hand, though the mind and "heart" play a large rôle in their accomplishment. If the surgeon be a real artist what he does is always meticulously and beautifully done, from arranging the light and the way the scalpel is

held to the final bandage. Shakespeare's Polonius said "the apparel oft proclaims the man." So too in surgery do bandages proclaim the surgeon. Untidy dressings frequently represent a "sloppy" performance within.

The craftsmanship of surgery when seen from without or when viewed in the foregoing light seems complicated and confused, and yet it is all based on extremely simple principles. The principles of surgery are all covered under anesthesia, hemostasis and asepsis. The surgeon who can avoid pain, lose a minimum amount of blood and keep the wound sterile can explore all the cavities and portions of the body with complete safety to his patient. Stated thus it appears a simple matter. Looked at seriously it presupposes an excellent knowledge of anatomy, physiology, bacteriology and pathology, a conscience that works when no one is present and an attention to detail and to care in the use of the hands that only a few have the diligence, ability and imagination to practice.

#### HEMOSTASIS

The problem of hemostasis arose with the first attempt to treat a wound. Discussions of hemostasis must have arisen long before even the medicineman or his prehistoric prototype had been set aside as a privileged person at the tribal camp-fire. It is still a much discussed matter, and it is the fear of hemorrhage that is the chief force in withholding major surgical procedures from the hands of quacks and charlatans. Massive hemorrhage, as may occur from opening the heart or the accidental wounding of a major artery, is a terrifying spectacle, yet no more disturbing than the slow and fatal oozing from the gum of a hemophiliac following a visit to his dentist. The control of hemorrhage has for at least two thousand years been a major problem in surgery. It still is a major problem though fortunately now one of prophylaxis rather than of therapy. For a thousand years it figured largely in philosophy, in fact, ever since it was first noted that as the blood ebbed forth the spirit departed. Could the spirit reside in the blood and why the "innate heat"? Speculation—bitter, prolonged and to scientifically trained minds foolish—waged a bitter battle until once and for all the great Harvey explained the circulation of the blood and the matter was cast aside by the philosophers and relegated to the surgeons where it was being diligently studied. Paré was credited with bringing the use of the ligature to aid the surgeon in hemorrhage, but Celsus spoke of it, and its exact beginnings are unknown. Certainly it was not in common usage until three hundred years ago, for boiling oil and the hot iron accompanied surgical procedures well after the days of Paré. Secondary hemorrhage due to sepsis may have been the chief reason why the ligature was not more widely used. Thus it was not

until Pasteur and Lister definitely outlined the rôle of bacteria in surgery that hemostasis in the modern sense was really practiced. When operations could be completed and the skin closed over buried sutures and ligatures, modern surgery began. Thus it required antisepsis and asepsis before hemostasis in the present sense could be achieved. But this came slowly. Although after 1846, through the precious discovery of anesthesia, the patient could be put to sleep and rendered insensitive to pain and though instruments and ligatures were at hand for controlling hemorrhage, and asepsis assured the healing of the wound, surgeons still hurried through intricate major procedures as in the days before anesthesia. The result of all this haste was incomplete hemostasis. In the case of a radical operation for the removal of cancer of the breast, the ordeal was put through in from twenty to thirty minutes. This made it impossible to care for all the bleeding points, it meant great slashes at the delicate tissue, it meant undue haste in the exposure so that traction on skin edges and in the wound was excessive, and it meant careless and often faulty apposition of the wound. Fortunately, a school of surgery characterized already as a "school for safety in surgery" arose in this country under the stimulus, guidance and example of the late William Stewart Halsted. He demonstrated that an operation lasting three and even four hours, if all the principles of surgery were utilized, did little harm to the patient. His painstaking devotion to hemostasis, to asepsis, to the delicate handling of tissue and to the artistic finish of his handicraft were of the greatest value to surgery. He introduced new hemostatic forceps with small jaws at the crushing points so that a minimum of tissue beyond the vessel was injured; he demonstrated the great decrease in the reaction in the wound when fine silk ligatures were used that included only the injured vessel, and his reapproximation of a wound attempted to bring together the tissues layer by layer as they belonged and without leaving dead spaces. His cases were a forcible demonstration of the fact that if the volume of blood is not diminished and the patient not otherwise traumatized, the duration of the anesthetic is of relatively little importance. This demonstration has been largely responsible for the disappearance of the "slap-dash" type of surgery so popular a short time ago in public operating theaters and so foolishly called in its day "dexterous" and "skilful." No serious major procedure can be accomplished without danger to the patient in the short fifteen to thirty minutes not so long ago thought to represent the maximum and optimum duration for such affairs. Naturally, I do not refer to emergency procedures where special reasons for haste may prevail, though even in these cases if more time is taken before operating to establish a satisfactory condition in the patient, the final results may be more satisfactory.

With such a clear demonstration of the status of hemostasis, its supreme importance and the inevitable, terrible sequelae which follow serious loss of blood, it is surprising that the application of this principle is not more rigidly adhered to. Failure to comply with this principle not only raises the danger of diminished loss of blood but means that the operative field is obscured. When one cannot see clearly what one is to cut, it is usually safer not to cut. To operate through a veil of blood is usurping God-like qualities, as if one could see through blood! Or it is placing too great reliance on a knowledge of anatomy or rather a misconception of anatomy since no two people are just alike. Thus the technical matter of the control of hemorrhage assumes a predominant rôle in surgery. To practice meticulous hemostasis requires great delicacy of touch, dexterity and manual perfection. Great dexterity alone, however, is insufficient if not backed by a full scientific appreciation of the task in hand. "Slapping" a lot of forceps hurriedly into a wound is not true surgical craftsmanship, and indeed as far removed from it as is the carpenter's job of hammering in a lot of nails. True craftsmanship here means the careful and accurate placing of the hemostatic forceps exactly on the bleeding vessel, which should be so isolated that only the vessel itself is clamped. This is better done when the vessel is clamped before division. To grab at a bleeding area hurriedly means the inclusion of many cells other than the vessel wall, all of which are to die if thus injured. The result is an indurated wound. Surgeons who have such wounds may well pause to consider the cause thereof.

Moreover, many surgeons use heavy strands of sterile preserved animal tissue, i.e., catgut and kangaroo tendon, for suture and ligature material. They should realize that this dead organic matter creates a large inflammatory reaction similar to that produced by destroying autogenous cells by rough handling of any nature. The reason given for the use of these heavy materials is that great force is often needed to reapproximate wounds. This argument, however, loses weight when one considers that the material through which the suture passes is living matter and that if great tension is used the living cells will die and thus the wound separate even if the sutures remain intact. Multiple fine sutures so delicate that they will break if used under great tension will accomplish the task better, and at no point will sufficient force be used to kill and cut through the living tissues. This lesson is seen in "Gulliver's Travels" when an infinite number of delicate strands satisfactorily held the (to the pygmies) giant visitor. This all emphasizes the handiwork of surgery, how important it is to clamp the vessel exactly, how vital it is to tie each knot securely, how necessary to place all sutures with meticulous care.

Moreover, it emphasizes further that great attribute of art—the correct selection of materials. The surgeon should be just as critical in the selection of scalpel and forceps as the artist in the selection of his brush, the sculptor in the selection of his hammer and chisel or the violinist in the selection of his bow. Those operators who are content to use poorly balanced knives, forceps with large crushing jaws, needles of a size and type better suited to shoe-leather than living tissues cannot succeed, since in their practice of the art they fail to utilize all possibilities. This does not mean that good surgery cannot be practiced without the most elaborate equipment. In fact, the real surgeon who understands the principles of his art will be enabled to accomplish creditably and safely a major technical operation with his razor, his wife's silk thread and a pair of "tweezers" from his toilet case. It does, however, emphasize how important it may be in a teaching hospital to have only the most perfect and delicate apparatus and instruments so that the young surgeon will from his earliest training learn finesse, delicacy and beauty in his work.

#### ANESTHESIA

Anesthesia is the second principle of surgery in chronological development. Surgeons of today cannot picture the terrible ordeal of operations before this great gift was brought to ease man's sufferings. The use of spirits or wine and of various soporific and analgesic drugs to alleviate pain antedates written records. But these were not entirely effectual, and the gift of general anesthesia, first as ether in 1846 and then as chloroform in 1847, opened up a golden era for surgery, an era unfortunately in its earliest days filled with the terror of sepsis and only reaching the rich fulfillment of its possibilities after the work of Pasteur and Lister was appreciated. Now the surgeon has at his command a vast array of anesthetic drugs, both drugs which induce sleep with complete freedom from sensation and those which by local injection or application may remove from the field of operation sensitivity to pain. The great matter for the surgeon in relation to these drugs is which to choose. He must suit the anesthetic to the requirements of the case in hand. But having done this, he must also see that it is administered correctly. Nothing is more disturbing to the surgeon than a poorly administered general anesthetic, and yet in no branch of their art do surgeons as a whole evince so little knowledge. Thus instead of being a mental as well as physical help at such times, they fret and worry their anesthetists by inept remarks and an incapacity for withholding their hands that is often *astonishing* and always lamentable. One draws the obvious deduction that surgeons should know more of both the art and the science of inhalation anesthesia. They should appreciate the alveolar tension of the anesthetic gas opti-

num for producing anesthesia. Then they would not insist on pouring on a uselessly high concentration which can serve no purpose except to irritate the patient. Furthermore, they should know all the manual tricks of this special form of their handicraft; how to hold up the jaw, why and when intranasal and intrabuccal apparatus is wise, how ether masks are best constructed and what are the tricks by which a worried child or nervous woman can be initiated to the anesthetic.

When it comes to the use of local anesthesia—whether spinal, conduction, infiltrative, or in whatever special form desired—one is again confronted with the problem of craftsmanship. Here again the use of the hands is the mechanism for producing the desired result. The way a syringe is held, the size and length of the needle, the preliminary and in some cases difficult but important infiltration of the corium all are matters of technical performance. Merely to “squirt” in several hundred cubic centimeters of procaine hydrochloride is unwise and sometimes hardly so efficacious in accomplishing the task as a far smaller amount of the drug correctly placed. The most sensitive nerve endings are near the skin; fatty tissue has a relatively sparse supply, and some viscera have none. Large amounts of a watery fluid greatly distend the tissues, and finer vessels are so stretched they may not function so that a relative anoxemia is produced. This may injure permanently cell life so that in addition to cells killed by the needle or by the fluid and also in addition to the great amount of fluid which must be carried away, there may be a tendency to local death of cells from this cause alone. All this damage creates a “wet” wound and in some clinics where careful hemostasis is not practiced wounds are not closed *per primam*. This is a serious reflection on the craftsmanship of the surgeon.

#### ASEPSIS

The third principle of surgery and the last to become established is asepsis. When dealing with this principle, the application of the art becomes of vital importance. Here one must consider the performance of the operation itself as well as all the preliminary processes of sterilization that precede the operation in order to bring to the wound nothing but sterile materials. This matter of sterilization is a chief province for the surgeon. Unfortunately, it has been largely delegated to nurse-assistants, but no surgeon of real standing can afford to operate in a hospital where he is unfamiliar with the methods of sterilization or relieved of responsibility for the proper performance of these important matters. Not so long ago surgeons benefited in this province by the fact that many operations were performed in homes where the surgeon himself personally saw to all the details of sterilization. Surgeons of another generation may escape such great labors in this province, but they can never escape the responsibility.

As concerns what happens in the field of operation itself, the surgeon has momentous and continuous responsibilities regarding asepsis. He will do well to recall the words of Arthur Tracy Cabot, "Every operation is an experiment in bacteriology." One cannot hope to keep any wounds free from bacteria but the entrance of virulent organisms or of too large a number of avirulent but pathogenic organisms can be prevented. This can be done only by the most assiduous care and constant attention to details. The art of surgery is nowhere better expressed than in the control of sepsis. It concerns the preparation of the skin, the draping of the field, the eye, which though always on the task at hand, never misses a "break in technic," the ability to see the tiny hole in an assistant's glove and the patience to wait until it is changed, the constant determination to see all hands before him lest some be hanging down in their natural position and therefore endangering their sterility, and the quick realization of a new and clumsy assistant whose nonsterile back touches the instrument table. Finally appear that exquisite handling of tissues, that delicacy and gentleness of touch, that care for the insensitive part which attempts to replace the protection given by now paralyzed nerve endings. All this care the surgeon knows means less injury to cells and therefore less "reaction" in the wound. Wiping with a dry piece of rough gauze, a ruthless treatment of delicate living cells, the content of which is largely water, will be done away with, and pads of cotton or gauze moistened in warm physiologic solution of sodium chloride will be used as gentle sponges, pressed on the part and then carefully withdrawn in order to injure as little as possible. Thus tiny thrombi will not be torn away and a larger thrombus engendered, and the cells will not be vitiated by dehydration.

Finally, in the closure, the greatest care will be taken in reapproximating the severed parts layer to layer, avoiding unnecessary tension and obliterating all "dead spaces." As the skin closure is approached, the subcutaneous tissue will be accurately held together in a somewhat elevated ridge so that no tension is brought on the final row of skin sutures. These latter may even be covered with some antibactericidal dressing, such as silver-foil, to seal off carefully the danger of further infection from the skin, a part that cannot be sterilized. Lastly, comes the dressing itself, neat, with just the right elasticity and compression, nowhere better described than by Hippocrates. And then the position in bed, on the side, with free room for respiration but in a position where vomiting does not mean that the upward explosion is followed by intratracheal insufflation!

There are other matters that concern the art of surgery, but which deal less directly with its craftsmanship. Transcending in importance all considerations not here dealt with and vital to the easy and correct

performance of what has been related is the position of the light. This might best be discussed under the caption of exposure. Hippocrates wrote:

The things relating to surgery, are—the patient; the operator; the assistants; the instruments; the light, where and how; how many things, and how; where the body, and the instruments; the time; the manner; the part.

This paragraph might well hang today in every operating room for it comprises in a short sentence the really important matters of the art of surgery, and it seems to emphasize particularly the light and the position of the patient. There is nothing more distressing to an experienced surgeon during a visit to the operating room of a colleague than to find his friend in a well lit operating room, but the patient and his assistants so placed that the wound is carefully shaded from the incalculable benefits of the excellent illumination. Only when the patient and operator are comfortable and the light correctly focused into the wound and the exposure ample can the principles of surgery be practiced in their most adequate form.

All these matters concern the art of surgery. They are the things surgeons accomplish with their hands. They must be exquisitely done, with dexterity, confidence, gentleness and even beauty if they are to reach their fullest expression. By constant practice perfection in this art is obtained, and by practice of the art, science makes its slow movement onward. It has been most unfortunate that in recent times in both popular and professional circles, science has been thought the more important matter. Let those who have expressed such ideas recall the history of science, how practice of the art, how experimentation, how trial and survival all preceded progress in science. Let them recall what happened to science for a thousand years when practice was neglected. Then will the art receive full and just credit for its share in the progress of human knowledge.

He in whose honor these papers are prepared has by his works and his example beautifully expressed the art in surgery. His technical performance, his craftsmanship have permitted him each day to create with his hands work of real beauty. The finesse with which he accomplishes each technical step, the great care devoted to tissue, the correct use of instruments and apparatus, the precision and dexterity of his handiwork have allowed him to explore an important field. In this special field, his studies have been of great value in furthering medical knowledge. Thus one views a concrete example of how practice of the art begets the science. To those privileged to watch the performance and study the results there has been bequeathed a great stimulus and the hope that diligent attention to the same principles may still further benefit the science. So will pupils ever follow the master.

## THE CEREBRAL CIRCULATION

### VIII. A QUANTITATIVE STUDY OF THE CAPILLARIES IN THE HIPPOCAMPUS \*

STANLEY COBB

The capillary circulation of the brain has received little attention from investigators of cerebral physiology. Although Hill,<sup>1</sup> in 1895, pointed out the relationship between the blood flow through the brain and its metabolism, it is only in the last few years that any quantitative studies of the blood supply to nerve tissue have been made. A comparison between the capillary bed of the brain and that of other organs is significant. Krogh<sup>2</sup> measured the capillaries in muscle and made a plea for more quantitative studies of this sort, saying: "I believe that when taken up in earnest by competent anatomists, the field of quantitative anatomy will prove to be a rich and fruitful one. Many determinations of vascular and glandular surfaces are urgently needed as a basis for quantitative physiological work."

In a previous paper,<sup>3</sup> I deduced from the published work of Wearn, Krogh and Craigie that cardiac muscle, when injected, shows 11,000 mm. capillary length per cubic millimeter; active skeletal muscle has 6,000 mm.; while muscle injected while at rest has only 2,000 mm. of injected capillary. In contrast to this, the gray matter of the cortex has but 1,080 mm. of capillary per cubic mm. These calculations are rough, but they indicate the great difference in vascularity between the tissues. In a general way, anatomists have long recognized that the gray matter of the brain, and the nuclear masses are more richly supplied with capillaries than the white matter. Pfeifer,<sup>4</sup> in his recent work, gave an admirable account of the historical development of the subject. He also described the general arrangement of the capillaries of the pia, brain stem and cerebrum, and illustrated his text with beautiful plates. He gave little attention, however, to the true vasoarchitecture of the cerebral cortex, and made but two brief attempts at quantitative study of the capillaries,

which will be discussed later. Craigie<sup>5</sup> believed that the richness of the capillary supply is directly related to functional activity, and his excellent work on the albino rat<sup>6</sup> showed that the nuclei of the brain stem are exceedingly vascular organs, much more so than the white matter; moreover, certain nuclei are much more vascular than others. He also made careful observations on the cerebral cortex,<sup>7</sup> and his quantitative studies show that the different cortical layers vary somewhat in the richness of their capillary-supply, the fourth layer (lamina granularis interna) being always the most vascular. He did not give any measurements of the the hippocampus.

The great work of the Vogts on cerebral architecture aroused widespread interest in the laminations of the cerebral cortex. Speculations as to the functional significance of these layers have been made; in 1914, Bolton<sup>8</sup> even suggested a reclassification of the psychoses on the basis of selective degenerations of certain cortical laminae. From Vogt's laboratory, one paper on vasoarchitecture has appeared, the great bulk of work from there having been concerned with the cytoarchitecture and myeloarchitecture. This paper on brain capillaries is by Lorente de Nò;<sup>9</sup> it describes and pictures the capillary network of the area striata, area peristriata and Ammon's horn. In the occipital cortex, the fourth layer is apparently the most vascular and, in Ammon's horn, the pyramidal layer, but capillary-measurements are not given.

The present study aims to contribute to the knowledge of the cerebral circulation by giving quantitative data concerning the capillary blood supply of certain laminae of the rhinencephalon of the rabbit. Capillary counts were made in three laminae of the hippocampus; the results are compared, and then all three are added and averaged under the name of "hippocampus" for comparison with counts from other areas. The terminology of Potter<sup>10</sup> is used, since her work gives the

cytoarchitecture of the rabbit. An exhaustive study of the rhinencephalon recently came from the laboratory of Vogt by his co-worker, Rose.<sup>11</sup>

The relationships of the various layers are confused by the convoluted form of the Ammon's horn, but, taking the dentate fascia as the outer surface of the structure (fig. 1), one finds from without inward: first, the lamina molecularis; beneath this, the narrow and not well defined lamina lacunaris, and between this and the conspicuous lamina pyramidalis, a wide layer mostly composed of dendrites from the pyramidal cells. They lie in even, radial formation, giving the name stratum radiatum to the layer. Close below this, as mentioned before, is the lamina pyramidalis, composed of large, rounded or oval nerve cells; the axons from these cells pass downward through the stratum oriens to the alveus. The layer of pyramidal cells curves slightly to its sharp bend, and then rolls inward to its end-plate, which is capped by the narrow, darkly staining granular layer of the gyrus dentatus. Not only is the anatomy of this part of the brain difficult to comprehend, but it has been made more so by the various nomenclatures used by different investigators. In this work, I have followed the nomenclature of Potter,<sup>10</sup> which is best illustrated in her plate IV. In order to correlate this nomenclature with that of other authors, a table has been made out, showing the number of laminae into which the Ammon's horn is divided, and the corresponding names used.

#### METHOD

Ten rabbits were used; after anesthetization with barbital or ether, the thorax was rapidly opened, and the heart and great vessels were exposed. The internal mammary arteries and the abdominal aorta were clamped. The pericardial sac was next opened, and an incision was made through the wall of the left ventricle. A cannula was inserted through this incision and carried past the aortic valves into the ascending aorta and ligated. The injection mass was then allowed to run in at a constant pressure between 200 and 225 mm. of mercury. A 2 per cent aqueous solution of "berlin blue" was chosen as the injection mass, after trials with other substances had proved less successful. Ludwig's old injection apparatus was used because with this one is able to control and record the injection pressure during each experiment. The amount injected into each rabbit varied between 150 and 200 cc. The berlin blue was injected while the animals were anesthetized, but still alive. Within five to ten seconds after the injection mass had started to flow, the animal was probably dead. The average time from the cutting of the skin until the cerebral vessels were filled with injection mass was from forty to sixty seconds.

The brain was rapidly removed and placed in 10 per cent formaldehyde. Blocks were embedded in celloidin and cut at 20 microns. The sections were stained lightly with 1 per cent carmalum, which brought out the cellular architecture and served as a suitable background for the blue of the injection mass.

11. Rose, Maximilian: Der Allocortex bei Tier und Mensch, *J. f. Psychol. u. Neurol.* 34:1, 1926.

In studying the sections, a square-ruled disk micrometer was used in a Zeiss ocular no. 2. The objective was a Zeiss "apochromat 4 mm." With this combination, each of the small squares measured 25 microns on a side. It was found convenient to use an area of twenty-five small squares (one-quarter of the whole). Thus, each capillary count was made on a cube of tissue 125 by 125 by 20 microns. This contains 312,500 cubic microns, or  $1/3200$  of a cubic millimeter. The actual measurements are, therefore, multiplied by 3,200 to give microns per cubic millimeter, and then divided by 1,000 to reduce the final figure to millimeters of capillary length per cubic millimeter of brain substance.

Fig. 1.—Low power photomicrograph ( $\times 38$ ) of general region of Ammon's horn, showing the layers and their relationship to one another and to the ventricle, from a section 20 microns thick; the injected vessels stand out black, the cells stained with carmalum are grayish (rabbit E-26-24C, slide VIII).

#### OBSERVATIONS

In the hippocampus, 1,500 capillary counts were made; ten animals were used, and in each animal areas for counting were chosen at random in each of three localities (fig. 1): (a) the lamina pyramidalis, (b) the stratum radiatum and (c) the granular layer of the gyrus

dentatus. It will be seen from figure 1 that (a) and (c) are layers packed with cells, while (b) has few cells and many fibers which radiate out from the pyramidal cell layer, giving rise to its name. Five capillary counts were made in each of these three localities in each of ten slides from each of the ten animals. The results are tabulated on the chart (fig. 2) to show the distribution and divergencies of the data thus accumulated. To get a general figure for the "hippocampus," all the 150 counts in each animal were averaged.

By reference to the chart, it can be seen that the average of all the observations falls at about 450 mm. of capillary per cubic milli-

*Comparative Nomenclature of Laminae (or Strata) of Ammon's Horn\**

meter of brain substance; this may be taken as a general rough estimate for the vascularity of the region of Ammon's horn, but, as Craigie<sup>12</sup> points out, one cannot with accuracy use the sum of the observations on various laminae to represent the whole thickness of the cortex. This was true in the region of Ammon's horn, where certain layers were too narrow and ill defined to be measured accurately.

Again referring to the chart, one sees that the lamina pyramidalis is more vascular than the granule cell layer of the fascia dentata, and much more vascular than the stratum radiatum. The average capillary length per cubic millimeter in the lamina pyramidalis is approximately 680 mm. The measurements for the granule cell layer of the dentate

12. Craigie (footnote 7, second reference, p. 101).

gyrus, another richly cellular structure, average 400 mm. per cubic millimeter. Lastly, the stratum radiatum, a fibrous layer, averages only about 300 mm. of capillary per cubic millimeter.

## CRITICISM AND COMMENT

Several fallacies may impair the accuracy of the measurements here recorded. In the first place, is the injection complete? Are all the capillaries filled? The fact that one animal (N-25-74) has distinctly higher values in all layers might suggest that more capillaries

Fig. 2—The measurements of capillary length in millimeters per cubic millimeter of brain substance are plotted for each of the three laminae measured in the Ammon's horn of ten rabbits. Lamina pyramidalis is indicated by crosses; stratum radiatum, by circles; the granule cell layer of the fascia dentata, by squares, and the average of all these three, called "hippocampus," by black dots. These are the uncorrected measurements as made from the microscopic slides.

were filled in this animal than in the others. All the animals were injected with an equal pressure, controlled by a manometer, so the pressure of injection could not account for the difference. Nevertheless, some unknown factor may have caused this animal to have more open capillaries than the others.

Fig. 3—Thick section, cut at 200 microns, to show completeness of injection. Cortex from the area temporalis inferior ( $\times 170$ ). The locations of the laminae are marked at the right of the plate (Potter, plate XVI). *I* indicates lamina molecularis; *II*, lamina granularis externa; *III*, lamina pyramidalis; *IV*, lamina granularis interna; *V*, lamina ganglionaris. Location of the cytologic laminae is derived from a neighboring serial section, cut at 20 microns and stained for cells. The plastic effect is obtained by making a negative print, slightly out of focus (method described by Pfeifer, footnote 4) (rabbit N-25-85D, slide 51).

Pfeifer pointed out that injections are usually incomplete, and that one must check the completeness of the injection by careful observation of the capillaries in thick sections. This has been done in sections cut at 200 microns, and in such specimens the vessels can be seen to branch out into capillaries which form a network of many loops (fig. 3). The vascular bed can then be traced on into other vessels of larger caliber. In this way, one presumably goes from venule to arteriole, or vice versa, but it is difficult in the injected specimens to distinguish between the two. From this point of view, the injections appear to be fairly complete.

Craigie<sup>6</sup> emphasized the importance of reckoning the amount of shrinkage. The rabbits' brains were all fixed in 10 per cent formaldehyde, embedded in celloidin and cut according to a routine technic. By measuring fresh brains of rabbits of equal weight, I estimated that the mounted specimens, as used for the measurements, had shrunk 10 per cent. To calculate the exact length of capillaries in fresh brain tissue seems well nigh impossible, for one has no way of telling whether the capillaries themselves shrink more or less than the surrounding tissue. These figures, then, must be taken only as approximations. They have, however, an unquestionable relative significance, showing that the cell layers, especially the lamina pyramidalis, have a much more vascular bed than the more fibrous layers. Also by comparison with measurements on other areas by Cobb and Talbott,<sup>3</sup> it is seen that the motor cortex of the cerebral hemisphere in the rabbit is somewhat more vascular than the Ammon's horn, the former having 515 mm. of capillary per cubic millimeter, and the latter 450 mm. The visual cortex seems to be even more vascular, with a capillary length of about 555 mm. per cubic millimeter.

Pfeifer,<sup>4</sup> in his calculations of the capillary content of brain substance, found for the rhinencephalon (at a point near the tractus olfactorius at the base of the brain, as seen in his fig. 36) a capillary length of 805.5 mm. contained in one cubic millimeter of tissue. In the gyrus lateralis (Pfeifer's fig. 43) of the cerebral cortex, he calculated 1018.7 mm. per cubic millimeter. His figure for Ammon's horn is not far different from my figure for the lamina pyramidalis, but it is distinctly higher; the figure for the gyrus lateralis is considerably higher. The discrepancy may be explained by differences in technic. Pfeifer did not say what pressure was used to inject his specimens, but he apparently used a hand syringe and high pressure. This may have opened more capillaries. Again, he made only two measurements and they were made from restricted, chosen areas. It may be that had he made many measurements and averaged them, his figures would have more closely approximated mine. Our data agree closely enough, however, to indicate that by this method a quantitative estimate can

be made of the capillary supply of the brain. Great as this capillary supply seems to be when figured out in length per cubic volume, it is small when compared to organs such as muscle. As Hill and Nabarro<sup>13</sup> said: "When compared with the muscles the brain is not a seat of active combustion." They considered that the brain has a low metabolism, but did not take into account the fact that the brain has

Fig. 4.—Photomicrograph ( $\times 85$ ) of a thick section (200 microns thick) of injected region of Ammon's horn of the rhinencephalic cortex. The layers are designated at the right: *A*, alveus; *O*, oriens; *P*, pyramidalis; *R*, radiatum; *M*, molecularis. It is obvious that the stratum radiatum is less vascular than the lamina pyramidalis. By focusing up and down, almost any vessel could be followed out into its capillary branches, through many loops and into another larger vessel, indicating rather complete injection (rabbit N-25-85D).

13. Hill and Nabarro: On the Exchange of the Blood-Phases in Brain and Muscle, *J. Physiol.* **18**:218, 1895.

a rapid blood flow, even in the prone position, according to Wolff and Blumgart.<sup>14</sup> When the head is raised above the heart, it would seem that the circulation would have to be even more rapid, because of the great decrease in venous pressure as compared to arterial pressure. Thus, it may be that the brain has a fairly active metabolism, though the comparatively scant capillary bed may not give such a wide margin of safety against anoxemia as is seen in the exceedingly vascular and variable muscle.

In this connection, it is interesting to figure out the area of capillary surface per cubic millimeter of brain substance, for it is this surface which is exposed to the cells and permits diffusion. The exchange between capillary blood and cell fluids is the essence of the metabolic process. In the lamina pyramidalis, calculations from the data given previously show that the capillary surface available for diffusion in a cubic millimeter of brain tissue is 10.3 sq. mm. For the stratum radiatum, it is much less, 4.5 sq. mm.; while for the granule cell layer of the fascia dentata, it is 6 sq. mm. per cubic millimeter.

## A NOTE ON THE ACADEMIC LIFE

EDWIN P. LEHMAN

The academic life, like the bricklayer's life, must be lived according to the lights of the individual. But there are in each of these, as in the life of a person of any grade or calling, certain elements that characterize it. And those that characterize the academic life have a charm and richness traditional in speech and literature.

Take, for instance, a professor of the classics. He is usually a personable man, with a mellow taste in books, music, pictures, fabrics and furniture, ready with a jest or a sober comment. He is a scholar of the first water, able to trace his roots and his terminations, a familiar of the heroes of his literature as well as of those creatures that burrow in the depths of libraries beneath the clear surface waters in which the rest of us splash. He is a teacher in the true sense, the man to whom youth comes for aid in interpreting experience in fundamental terms. His lecture hour is a delight. From the line of Virgil or the dialogue of Aristophanes, he makes live the man or the times in a modern frame that relates the one or the other closely to the experience of the modern group before him. To him comes the puzzled individual student for advice, worldly and spiritual alike, comes and returns, clarified, soothed, invigorated, inspired, as the occasion demands. In short, he is a product of his life, the rich academic life of tradition.

His is a life long envied by the thoughtful, by those in love with self-development and contemplation. He has certain fixed duties: six, ten or twelve hours of teaching each week—teaching that he enjoys, in a field that is as familiar to him as the outlines of his own hearth. He has been over it again and again, has each lecture solidly built, cleverly and neatly articulated, polished to a degree of surface brilliancy; has, traditionally, even his jests placed in the texture of the whole like an inlay of nacre in a cabinet of rosewood. It is true that this has required labor, but the labor is far in the past. Today he needs only a touch here and there to bring his presentations up to the level of current thought. The substance changes little from year to year. Research is directed largely to the details of philology and to the search for sources, material not often to be allowed to confuse undergraduate students. The main structure of his subject is more or less fixed. If he has graduate students, his labors may be somewhat increased. But the number of such students is apt to be small, and their needs can be met at an academic pace.

To his teaching duties, which he must regard as his most insistent responsibility, there are added certain executive functions, thereto closely

allied. He may be a member of a number of committees, two or three, perhaps, devoted to the conduct of his university or to the definition of its educational policies. These he may or may not find interesting, but their sessions are apt to be infrequent, and the preparation therefor is often insignificant. Occasionally, no doubt, a true chore is present among their functions. He has also the development of his department to accomplish, the task of interesting promising youngsters in his subject, the finding of teachers for his junior positions, the distribution of their time and the encouragement and inspiration of them toward scholarship and scholastic productivity. But these are, essentially, teaching problems, a part and parcel of the task of his life that he has chosen for its appeal to his imagination.

Between the hours of these tasks he has leisure. Some of his days may be entirely his own. On others, he may find the after breakfast hours free or the hours of the late afternoon. No man, perhaps, is better qualified to dispose of this delightful independence of the fixed duty. He can make his freedom productive, whether he spends it in communion with books or with himself. Productive scholarship is notoriously temperamental. There are periods of intense activity and periods in which the mind lies fallow, gathering strength and subtlety for the fresh attack. Imagine the delight of a certain knowledge that if the seed does not sprout today, tomorrow is an equally fecund springtime. Imagine the joy of seizing for the harvest the golden moments of morning before the day's work has blunted the edges and dulled the facets of the mind.

The life of the professor of the classics may not be all such academic beer and skittles. There may be problems to solve within and without his academic sphere—problems dependent on personality or the harassing riddles of bread and butter. But his life is built on a foundation, the corner-stone of which is opportunity for contemplation and the birth of the fruits of contemplation.

Behind the full time idea in the teaching and the clinical branches of medicine, there lurks not a little desire for such a life. It was, in part, to give the teachers of medicine in its various divisions the opportunity for contemplation that they were taken from the lives of busy practitioners and placed within the walls of hospitals and laboratories. There they were to divide their time between the classroom, the ward, the laboratory and the library, much as they saw fit.

Let us compare, then, the life of the professor of surgery, the surgeon dedicated to the academic life, with that of the professor of the classics. In the first place, his appearances in the classroom may be more or fewer than those of his colleague. It is not in the number that the difference lies. There is no such thing as adequate preparation for much of his teaching. In his bedside rounds, his dispensary, he

may be confronted, without warning, by a condition that he has encountered but once or twice many years before; and in that emergency, he must produce a knowledge that will relate the condition to fundamental principles of biologic change and so impress the moment and the material on his students' minds. It may be that these fundamental principles have been so developed in the interim that he himself must learn a new conception of the disease as he teaches. It is, in fact, in the rapid development of knowledge in the biologic sciences that the chief difference between his teaching and that of the professor of the classics lies. He must be aware, in some small part, of an enormously enlarging field of knowledge, increasing continuously and rapidly. And his relatively small awareness is, in itself, an enormous task. *Each fixed lecture must be reshaped, perhaps entirely rebuilt, each year; and each case he sees in his rounds of the wards must be interpreted on the basis of new facts.* These come to him from his reading, largely of the medical periodicals, of which the name is legion and of which more shall be said.

His executive functions add further to the balance against him and in favor of his colleague. He, too, will take his place among the committees of his university; but to them will be added committees more nearly related to his proper work. His department cannot function, his clinical material will fail, if his personal interest does not extend to the management of his hospital and of his dispensary, and to the conduct of the school for nurses. His thumb must be in every pie. And the affairs of these committees often mean laborious hours of preparation. To these tasks the professor of the classics has nothing to compare.

The development of the personnel of his department is, again, a larger problem. In numbers, his juniors may outweigh those of his colleague by five to one. Some of these, the interns, may be regarded as in some sense graduate students. But they are more than that, for on their presence and efficiency the operation of the department depends, just as much as on the presence and efficiency of the chief. Without interns there can be no clinic. The gathering of a staff of, perhaps, twenty men of ability is not a mean task in itself. In addition, they must all be given opportunities to learn commensurate with the grade of their development, opportunities which will satisfy at least the most able of them, so that, leaving or remaining, their tongues will be loud in praise of the clinic. Only so can other able men be attracted. This must be done often in the face of inadequate clinical material, and with limited laboratory space and equipment.

After the fulfilling of corresponding functions, it has been seen that the professor of the classics dips into his leisure, plunges into his research; not so, the professor of surgery. Indeed, I have barely begun to enumerate his responsibilities. Because it has no counterpart for his colleague, I have not yet touched on his most important duty, the task

most congenial to him, most germane to his calling, namely, the care of the sick. He must see to it that the organization of his wards and of the routine of hospital and dispensary is perfected, and that, once perfected, it is always lived by, completely and without fail. Diagnostic procedures and treatments must be undertaken or delegated. In any case, they must be carried out on proper indications and by proper methods. If a patient suffers from the failure to carry them out or from improper procedures, it is ultimately the chief's responsibility. All this means a degree of attention to detail and an incessant alertness that add to the burden of the hours.

He has a laboratory branch of his service; the administration of an additional institution rests on him. The obtaining and allocation of his budget, the equipment and repair of his laboratories, the discovery and proper use of technical and professional personnel and the acquisition of supplies and experimental animals—these matters must engage a part of his attention. Many of them are, of course, to be delegated, but his guiding hand must be at the helm. Another duty of the laboratory no one can take from him, namely, the guidance and inspiration of the investigations there undertaken. In order to get the best from his men, he must be completely familiar with all the details of their work. He must try to think one step ahead of them. The laggard must be spurred, and the stimulating research must be commended. In addition, in the back of his mind must lie unsolved problems, promising "leads," ready for instant suggestion to the student who comes empty of original ideas but eager for active inquiry.

Most of these demands on the professor of a clinical branch have only indirectly to do with his personal development. In spite of their multiplicity, he could so arrange his time that truly academic opportunity for isolation and contemplation could be his. In truth, the full time professor has often undertaken his task with the delightful anticipation that these would be his only duties, and that leisure would be added into his day for productive purposes. Alas, he did not count on the operation of a fundamental law of medical life in his supposedly cloistered paths. And the operation of that law may and often does completely deny him leisure, and always denies him the rich sort of protracted and continuous leisure that his colleague in the classics enjoys.

It is a truism to state that physician and patient stand in an intensely personal relationship; and yet that is the everyday law the operation of which has been underestimated so often. If a clinic is to thrive, to accomplish all that it can in the relief of suffering and to command adequate material for teaching and for study, it must stand well in its community. All ranks of society and all financial ratings must look on it with favor. Those on whom its charities are showered regard it with gratitude and with affection. Those by whose generosity such

charities are supported give it their profound respect. A clinic cannot win such a place in the community unless the members of its staff, not least the chief, have won their spurs before the lay world as physicians. They are good physicians. They meet the public, rich and poor alike, as friends. The exact quality and intensity of the lay reaction to the physician can hardly be appreciated even by the physician who is most successful in eliciting it. Furthermore, it cannot be elicited without time and effort expended in a long series of individual contacts, no matter how winning and how prepossessing the physician. It cannot be born of scientific eminence alone. It is the stuff from which successful practice is woven. In other words, the academic surgeon must be a busy practitioner. He must accept the time-consuming and altogether kindly tasks that mean success in private practice. He must expend as much effort and time in calming the parents of the spoiled child, in softening the announcement of a hopeless prognosis to a despairing wife, in readjusting the outlook of the emotionally disturbed and in cheering the still suffering convalescent, as though tomorrow's food and clothing depended thereon. He does it, of course, for his clinic, not directly for himself. But the effect is the same. In one sense, this necessity is not without merit, for the judgment that he knows not the woes of private practice and hence does not appreciate the point of view of his consultants can never justly be brought against him. Furthermore, his life is the warmer for all this; this is the laboratory of human emotion. There remains the fact, however, that this is the one unavoidable morass that swallows up his leisure. Never can he bury himself in his books or immerse himself in his reagents with the knowledge that before him lie four hours of steady and productive toil. Before these necessities flees from his life all academic quality.

He has some leisure, no doubt. This he must first apply, at all costs, to his current reading. He must be ready for the daily task, the unexpected nature of which must not surprise him. One cannot say how many journals he must keep in touch with. Suffice it that many pages a day can easily be a minimum. One distinguished physician, whose life is as full as a life can well be, starts each day by an early morning stint of at least fifty pages. Few active men can accomplish so much. But every active man, academic or nonacademic, whose work makes use of the constantly developing product of other minds, whose own mind loses not its plastic quality and whose conscience is not made to suffer by knowing that he is doing less than the best for his patient, must spend some part of each day so employed.

And now our professor of surgery is free for research, for the richness of his academic life, for the labor that to him is most fruitful. Need the contrast between him and his colleague of the classical department be drawn more finely or emphasized more strongly? The wonder

*LEHMAN—THE ACADEMIC LIFE*

is only that there are professors of surgery whose productivity is not diminished. Usually that productivity is the result of a union of the chief's ideas with the ideas and the long hours of labor contributed by his juniors. One wonders, often, what full time in itself has brought the professor of a clinical subject except an independence of financial reward that breeds honesty of judgment. Assuredly it has not inducted him into the academic life.

# TRAUMATIC ARTHRITIS

## HISTOLOGIC CHANGES IN HYALINE CARTILAGE

M. N. SMITH-PETERSEN

The term traumatic arthritis is commonly applied to joints which have been involved in an acute direct trauma, trauma secondary to fracture or trauma secondary to dislocations, particularly recurring dislocations. The term conveys a purely clinical picture since none of these conditions justifies removal of hyaline cartilage for histologic study. This statement is true with one exception only, that of recurring sacro-iliac strain. In arthrodesis of the sacro-iliac joint for relief of recurring strain, an ideal opportunity offers itself for histologic study of hyaline cartilage repeatedly exposed to trauma. The type of trauma involved is abnormal pressure resulting from disalignment of irregular, normally congruous surfaces. By such disalignment, prominences become apposed and consequently exposed to abnormal pressure (figs. 1 and 2).

In order to determine the appearance of surfaces of the normal sacro-iliac joints, sections were obtained from autopsies on persons without a history of sacro-iliac disorder. Photomicrographs of these sections are shown in figures 3, 4, 5 and 6.

A section of the iliac surface of the joint of a person, aged 17, is shown in figure 3; the surface of the joint is smooth, the cartilage cells are evenly spaced and the matrix stained uniformly. Figure 4 is a high power photomicrograph of a section from a person, aged 20, with essentially the same characteristics as the section from the patient, aged 17: smooth surface, even distribution of cartilage cells and uniformly staining matrix.

Figure 5 is a high power photomicrograph of a section from a person at the age of 40. There is not a great deal of difference between this section and the one from the patient aged 20. The cells are a little more closely spaced, and the matrix stained less uniformly.

Figure 6 represents the surface of the iliac joint of a person, aged 70. There is not any question as to the degenerative changes: irregular joint surface, cartilage cells unevenly distributed and matrix showing marked replacement fibrosis.

Comparison of these normal sections with sections from persons with a history of recurring strain or disalignment shows that traumatic arthritis is represented by the following histologic changes in hyaline cartilage: surface fibrosis, myxomatous degeneration of the matrix, replacement fibrosis and calcification.

Fig. 1.—Normal alinement of sacro-iliac joint. *A* indicates ileum; *B*, sacrum; *C*, joint cartilage; *D*, posterior iliac ligaments.

Fig. 2.—Disalinement of right sacro-iliac joint. *A* indicates cartilaginous prominence against cartilaginous prominence.

Fig 3—Photomicrograph of section from the iliac surface of the joint of a normal person, aged 17.

Fig. 4.—High power photomicrograph of section from the iliac surface of the joint of a normal person, aged 20.

Fig 5—High power photomicrograph of section from the iliac surface of the joint of a normal person, aged 40

Fig. 6.—Photomicrograph of section from the iliac surface of the joint of a normal person, aged 70.

Fig. 7.—Photomicrograph of a section from the iliac surface of the joint of a person, aged 20, with traumatic arthritis.

Fig. 8.—Photomicrograph of a section from the iliac surface of the joint of a patient, aged 35, with traumatic arthritis.

— a section from the iliac surface of the joint of a  
age 40, with traumatic arthritis.

Fig. 10.—Photomicrograph of a section from the iliac surface of the joint of a patient, aged 60, with traumatic arthritis.

Fig. 11.—Photomicrograph of a section from the iliac surface of the joint of a patient, aged 35, with traumatic arthritis and pathologic calcification.

A section from the surface of the iliac joint of a person, aged 20, is shown in figure 7. Marked surface fibrosis and myxomatous degeneration of the matrix are noted, as well as replacement fibrosis. The tendency of the cartilage cells to nesting is indicative of degeneration of the matrix. Compared with the normal (fig. 4), the degenerative changes are striking.

Figure 8 represents a section from a 35 years old patient. The outstanding changes in this case are the irregular joint surface and the replacement fibrosis. Comparison with the normal sections reveals that the changes are even more marked than in the 70 year old patient (fig. 6). The same holds true in the section from the 40 year old patient (fig. 9); nesting of cartilage cells due to degeneration of the matrix is beautifully demonstrated. The section from a 60 year old patient (fig. 10) shows complete replacement fibrosis of the matrix and few cartilage cells remaining. To illustrate the final change, that of calcification, a section is shown (fig. 11) from a 35 year old patient: There is marked irregularity of the osteochondral junction and pathologic calcification.

#### CONCLUSIONS

1. From a comparison of sections of the sacro-iliac joint in normal persons with those from patients with a history of recurring strain of this joint, one may conclude that hyaline cartilage in traumatic arthritis undergoes the following changes: surface fibrosis, myxomatous degeneration and replacement fibrosis of the matrix. In long-standing cases, calcification also occurs.

2. Changes due to age in hyaline cartilage are similar to those of traumatic arthritis. This is consistent, since age represents trauma extending over a period of years.

# THE VELOCITY OF THE GROWTH OF FIBROBLASTS IN THE HEALING WOUND \*

SAMUEL C. HARVEY

Certain characteristics of the healing of the simple incised, uncomplicated wound are, of course, familiar to the surgeon, and have been so since his kind first intelligently observed such a wound from day to day. Its edges "agglutinate," or become adherent to each other through the clotting of the blood. The strength of this adhesion is not sufficiently great for the first two or three days but that a minimum strain will separate the edges. If such is likely to occur, it is necessary to reinforce the "agglutination" with sutures. In from five to eight days it has become solidified, when, unless the strain on the wound is unusually great, the reinforcing action of the sutures is no longer necessary and they are removed. In from eight to twelve days, the strength of the wound is such that it meets the ordinary exigencies of daily life, and toward the end of this period it has become a scar. Such is the impression that the surgeon has received from his experience, and it is sufficiently correct for the meeting of the practical demands in the care of a wound.

When microscopic methods of study became available, this phenomenon was studied and visualized in terms of the behavior of cells. It became known that certain groups capable of phagocytosis serve to clear up the debris of dead matter, while others multiply in the fibrin network of the clot, forming connective tissue, and still others have to do with the growth of new blood vessels, thus completing the process of organization. This phenomenon as a whole can be divided roughly into two phases: that in which the exudative reaction is most marked, and that in which the proliferative reaction is predominant. Furthermore, when the amount of necrotic tissue is the least, then the exudative reaction is minimal, leaving the fibroplastic process to bridge the gap between the healing surfaces, the vascularization of the new tissue going hand in hand with its formation. The continuity of the injured part is reestablished, and the laying down by the fibrocytes of collagenous material in fibrils results in the cicatrix of adult connective tissue. This additional knowledge enables one to understand better the processes which are involved in the healing of a wound, and to speak of these in terms of cytology rather than in those of gross morphology.

It is apparent that the master reaction in this process, to which the clearing up of the debris and the bringing in of nutrient material by .

the new blood vessels are subsidiary, is that of the multiplication of the fibroblast. Cells of other types may be involved but they are transitory and relatively ephemeral, while the fibroblasts originate, divide and achieve maturity in direct continuity with the wound. One can justifiably conceive of them as an aggregate similar to an organ, an individual or a population, which follow definite laws as to their behavior determined by forces inherent within themselves or environmental. Certain of the phenomena in respect to growth have been thoroughly studied and might well be applicable to the multiplication of the fibroblast in the healing wound.

Chart 1.—Growth curve of the rat; after Brody and Pearl.

Any metazoan is an aggregate of cells, starting from one and increasing in number until the maximum of mass which is peculiar to that animal is attained. If the successive increments of mass and time are plotted in a graph, of which the abscissa represents time and the ordinate mass, a curve is obtained which visualizes the velocity of growth<sup>1</sup> (chart 1). It is at once apparent that growth starts slowly, increases progressively and regularly in velocity to a certain point and then in a similar manner decreases approaching an asymptote which is the maxi-

mum weight attained by the rat. If similar determinations are made on so common a gourd as the fruit of the pumpkin vine (chart 2), a graph which is almost identical is obtained. It would seem then that cell aggregates such as make up plant and animal life have a common trend as regards velocity of growth.

When individuals are grouped together within a limited space they make up an organism which, as Malthus pointed out long ago, obeys certain laws of growth. In recent years such populations have been studied experimentally and data of precision obtained. The fruit fly is particularly susceptible to such investigations and a graph is readily

Chart 2.—Growth curve of the pumpkin; after Brody and Pearl.

constructed in which the velocity of growth of the population is visualized (chart 3). Again the curve is a sigma as it is likewise if a yeast, bacterial or protozoan population be studied in the same manner (chart 4). This would seem to indicate that the velocity of growth changes in a similar fashion whether the units of the group being studied are closely bound together as an individual, as an animal, as a plant, or loosely as in a population. This is not irrational, for a unit of life such as a metazoan is by definition a population of cells.

From what has been seen thus far such behavior might be thought peculiar to living matter, one of the characteristics of which is reproduction. It is not, however, for it is well known in certain chemical

Chart 3.—Growth curve of fruit fly population; after Brody and Pearl.

Chart 4.—Growth curve of yeast population; after Brody and Pearl.

reactions in which the process is in itself catalytic<sup>2</sup> (chart 5). An instance of this is the hydrolysis of methyl acetate. This dissociation liberates acetic acid which accelerates the hydrolysis; the reaction is autocatalytic. When the products accumulate sufficiently, they interfere with the reaction so that the velocity of the hydrolysis is progressively diminished. Consequently the curve shows an autokinetic, or accelerating velocity phase, an inflection point and an autostatic or decreasing velocity phase. The hypothesis and the verification of it is an easy thing in the case of the dissociation phenomenon of methyl acetate, but a different matter in the similar behavior of the living organism.

Chart 5.—Curve of transformation in an autocatalyzed monomolecular reaction; after Robertson.

The unicellular organisms present the simplest problems for a similar analysis. Assuming a constant rate of division for a given unit of time,  $y$ , then the multiplication of the unit  $x$  will go as follows,  $1x/1y: 2x/2y: 4x/3y: 8x/4y$ , etc. In other words, the time increases in an arithmetic series, the number of units and consequently the mass in a geometric series. When this is plotted out, a parabolic curve like that of the early portion of the autokinetic phase of the dissociation curve of methyl acetate is seen. Experimentally, however, such a progression is not followed, for the time elapsing between successive division of the organism varies so that the series may read,  $1x/1y: 2x/2y: 4x/2.5y: 8x/3y$ , etc., which obviously produces a marked increase in the velocity

2. Robertson, T. Brailford: *The Chemical Basis of Growth and Senescence*, Philadelphia, J. B. Lippincott Company, 1923, p. 77.

of growth; or the reverse may be true, as  $1x:1y:2x/2y:4x/3.5y:8x/5y$ , etc., with a resulting decrease. The former is analogous to the auto-kinetic phase of the mononuclear autocatalytic reaction, and the latter to the autostatic phase. Lest one reason falsely from analogy to cause, in the living organism, it is better to speak of these as the phases of accelerated and retarded velocity, respectively. Thus when infusoria or bacteria taken from a culture that has attained its maximum population are transplanted into a fresh suitable environment they do not immediately take up an accelerated velocity of growth but show a lag.<sup>3</sup> This suggests that with successive division the organism produces within itself a growth accelerating factor, which quickens the rhythm of division to a maximum velocity. Once this is established, it may be maintained by successive transfers to fresh mediums, so avoiding the concentration of products produced by the organism, the decreased supply of nutrient material, and the increased density of population, all or any of which may act as growth retarding factors. In the metazoa the nutritive factor is readily maintained constant, so that the curve of growth of the normal rat, for instance, shows a decreasing velocity as a result of the other growth retarding factors.

In the illustrations of this curve that have been so far shown, the point of inflection has been fairly symmetrically placed; it has lain not far from a point midway between the two asymptotes of the curve. It is apparent from what has been said, however, that this is not necessarily true, for the growth retarding force may well become dominant early in the time period. As a matter of fact, in mammals it occurs at approximately one fourth of the maximal weight, and it is possible under certain conditions for the velocity to decrease progressively from the start. The appearance of the curve then suggests an abrupt initiation of growth.

This is seen in the regeneration of the tail of the tadpole when the increasing length of the new tail is plotted against time, as was done by Thompson, thus giving a velocity curve of growth<sup>4</sup> (chart 6). The point of inflection, if there is one, lies below the observed data, and the curve may be extrapolated in two ways. Durbin,<sup>5</sup> whose material Thompson used, in similar experiments on larger tadpoles provided further data (chart 7) which bring the point of inflection into view, but still early in the curve. It is then, under certain conditions, possible to obtain a curve of growth which shows only the growth-retarded phase.

It would seem probable from the comments thus far that the healing of a wound may be correlated with what is already known concerning growth. Moreover, it is apparent that in the changes taking place in a wound during the first ten to twelve days the dominant factor is the fibroblast. Mensuration of the increase in numbers and mass of these should provide a curve of velocity of growth which might rationally be compared with that of growth in general. Unfortunately, this is difficult to do, for the direct determination of this mass is obviously impossible and the counting of the units, well nigh so, although this has been attempted by Spain and Loeb<sup>6</sup> in a surface wound. Carrel<sup>7</sup> and those working with him<sup>8</sup> have used the surface area of a wound as a measurement of the velocity of healing, but this is difficult to resolve into its components; namely, the proliferation of fibroblasts and of epithelium, together with the contraction of the area as a result of the maturation of the process. Moreover, the variable of infection is uncontrollable except in the hands of such a master of technic as Carrel. He has also ascertained many important facts concerning the growth of tissue by culture in vitro, but the artificial maintenance of suitable nutrition, if nothing else, makes it impossible to determine the velocity of fibroblastic growth under the conditions of a simple wound. Nevertheless, he has succeeded in establishing certain important facts which will be discussed later in this paper.

It is desirable, then, to use some function of this cell which can be measured in situ. Tensile strength is a characteristic of connective tissue and it may be safely assumed that within the period of observation of twelve days, this may be used as a measure of its growth and maturation.

In work previously published, my collaborators and I gave the results of such experiments performed on the dog.<sup>9</sup> In brief, simple incised wounds were made in the stomach, fascia, muscle and skin of this animal; the accretion of the tensile strength was determined by killing animals at appropriate time intervals, and mensuration of it was carried out on a thread testing machine. The results, while somewhat crude and too few in number, were highly suggestive. The observations on these various tissues were reduced to a common denominator and the

velocity curve plotted (chart 8). It appeared that there was a definite lag period of between three and four days followed by an abrupt rise of the curve following which the velocity decreased progressively until the asymptote was reached. A similar curve constructed from the data obtained in a wound of the stomach, however, suggested that there might be an autokinetic phase. The observations were too few, however, to draw any generalization as regards this, and further experimentation on this animal, too costly. For this reason and because the rat is an animal whose growth and dietary requirements have been much studied, further investigation was transferred to this animal.

Chart 8.—Curve of tensile strength in healing wounds of dog.

#### EXPERIMENTAL WORK

The healthy adult white rat of known pedigree was chosen and was placed on a standard maintenance diet for a sufficient time to ensure that he was not suffering from any insufficiency. The operative procedure was performed under ether and the rat allowed to feed as soon as he desired, which was uniformly within twenty-four hours. It is then scarcely possible that the nutrition of these animals affected in any way the experimental results.

The stomach was chosen as the site of the wound for several reasons. Wounds of the parietal tissues such as muscles, skin and fascia, as were

used in the dog, are difficult to maintain uniformly uninfected. These tissues are of small dimensions in the rat so that the breaking strength of the wound could not be obtained with sufficient accuracy by the apparatus available. On the other hand, the stomach of the rat, as in all healthy animals including man, heals *per primam* and without evidence of infection such, at least, as to interfere with the healing of the wound. Moreover, should gross infection occur it would be apparent in the peritoneal cavity on autopsy and the experiment could then be discarded.

The method adopted for the testing of the breaking strength of the wound was that of distention of the stomach with air, the pressure being measured by a mercury manometer recording on a revolving drum. It was thus easy to obtain a permanent record calibrated against the manometer. The breaking point was always sharply defined by an abrupt drop. In carrying out this test the stomach was removed from the animal, after killing it with ether, the esophagus tied, a cannula inserted into the pyloric end and connected with the source of pressure. The air was admitted at a uniform rate, as shown by the slope of ascent of the curve on the record of the experiment, and this was constant in all cases. The stomach was moistened with physiologic solution of sodium chloride during the test which was always carried out at once after killing the animal.

In order to ascertain the range of breaking strength of the normal stomach, about sixty rats were used. It was found to have a mean of 160 mm. of mercury with a standard deviation of about 30. No consistent variation was found referable to age, weight, sex or condition of the rats though they were selected at random, in contradistinction to the choice of those used in the experiments in the healing of the wound. In the latter, the standard deviation of the data from the mean of the results was of the value of 10 per cent, with the exception of observations on the fifth day which were somewhat higher. Eight animals were used for each unit of time, which was twenty-four hours, the experiment being carried over ten days. The animal was anesthetized with ether, an incision made through the abdominal wall under aseptic technic, the stomach brought into the abdominal wound and an incision of uniform length (1 cm.) made in its anterior wall, extending through all layers, at the juncture of the distal one third of the stomach with the proximal two thirds. This was immediately closed with two layers of no. 000 plain catgut, care being taken to obtain good approximation, with peritoneal surfaces in apposition. The abdominal wound was closed with two layers of black silk. Sections were taken in each instance and studied for a control as to the presence of a normal process. The outstanding reaction was, of course, the formation of fibrous tissue. When plotted in a graph (chart 9) of which the abscissa represents days and

Chart 9.—Curve of velocity of growth of fibroblasts in healing wound of the stomach of the rat.

the coordinate pressure necessary to break the wound, a curve is obtained closely resembling the composite curve previously worked out on the dog.<sup>10</sup>

The suture material confuses the observations for the first two or three days, and consequently these data have been discarded. However, from previous experiments by Howes<sup>11</sup> it was found that the catgut loses all of its tensile strength well before the fourth day and consequently the curve is plotted from that point.

Extrapolation without further data is unsafe, and therefore it cannot for the moment be definitely determined as to whether the first four days represent a true autokinetic phase or an actual "lag" in the onset of growth. It is probably the latter in greater part. The velocity of division of the first fibroblast is low and is dependent on certain stimulatory factors in its environment, among which, as has been shown by Carrel and Baker,<sup>12</sup> is protease. This is a product of the digestion that the phagocytic cells initiate in the reaction to injury. It makes an interesting hypothesis to suppose that the sequence of events is the presence of dead material in the wound and broken down protoplasm leading to the invasion of phagocytes which act on it forming protease which in turn stimulate the fibroblast to divide. This would be effectual on many fibroblasts at the same moment, so that the start would be analogous to the massive inoculation of bacteria into a culture. If this should be the case, a lag period while this mechanism was developing might reasonably be expected. In addition, the tensile strength would not be apparent until the fibroblasts had "interlocked" across the wound space.

Certainly if there is an autokinetic phase it is brief, and this is readily demonstrated by determining the velocity constant of the composite dog and rat curves which is approximately 1.5 and plotting the curve as an autokinetic one, of which the equation is of the form  $W = Ae^{kt}$  (chart 10). Any attempt to shape the resulting curve to the one based on the data is ineffectual; in fact, it is the mirror image of it suggesting that the velocity of growth is definitely decreasing throughout the experiment. This agrees with the observations of Carrel and du Noüy<sup>13</sup> in the healing of a surface wound where there is a latent period of from five to seven days, ended by an abrupt initiation of the healing with the

10. The data obtained in these experiments and further details will be given in a future publication.

maximum velocity. This also agrees with the curve as produced by Thompson<sup>4</sup> of the regeneration of the tail of the tadpole.

It is apparent from an inspection of the curve that the velocity of growth is constantly and progressively diminishing until a maximum strength is attained. In other words, the healing of such a wound involves the autostatic or growth retarding phase of the growth curve alone. The multiplication of the fibroblasts is held "in leash" so to

Chart 10.—Composite curve of velocity of growth of fibroblasts in healing wounds of dog and rat; computed as a "growth-accelerating" phase does not correspond with curve plotted from data. The latter is obviously a "growth-retarding" curve.

speak and carefully brought to the exact strength necessary for the forming of the cicatrix.

This strength, with the period of observation in these experiments, is a relatively constant thing. In the dog, in all tissues examined—skin, muscles, fascia and stomach—it approximated a tensile strength of roughly from 2,000 to 2,500 Gm. to the centimeter of the linear wound.<sup>9</sup> In the stomach of the rat as in the dog, this reaches the normal strength

of that organ, which is that of the submucosa. This is shown by the fact that with the stretching of the stomach the peritoneum, mucosa and muscle rupture before the actual bursting of the submucosa. The strength of a wound at the end of this period of observation is that of a fibroplastic process, in other words of connective tissue, which is approximately uniform for all tissues studied.

#### SUMMARY

The tensile strength of a healing wound is a function of the multiplication and maturation of the fibroblasts.

There is a latent period of approximately four days before growth becomes appreciable in the terms of this function.

The velocity of growth, as so determined, starts abruptly at a maximum and progressively diminishes in rate.

The curve of the velocity of growth is closely analogous to the autostatic or "growth-retarded" phase of growth in general, and approaches an asymptote which represents the strength of connective tissue of the age of from 10 to 14 days.

# OVARIAN FOLLICULAR HORMONE

A PRELIMINARY COMMUNICATION \*

JAMES C. JANNEY

The work of a great number of American and European investigators during the past few years has focused the attention of the medical profession on the problem of ovarian function. Many theories have arisen, but so far there has been little unanimity in the acceptance of any one of them. The one piece of work with which this communication is concerned is that of Frank<sup>1</sup> and his co-workers in isolating from the blood of women an active estrus-producing substance. Frank has used the vaginal smear reaction of Stockard and Paponicolaou<sup>2</sup> as the criterion of the activity of his extracts.

Frank's work includes also theories of ovarian physiology, but this paper is concerned only with the reliability of the test as an index of ovarian activity. Theoretical considerations will not be taken into account at this time. The test in itself offers an extremely promising weapon for the investigation of ovarian function, not only from the theoretical point of view, but for the clinical investigation of many menstrual difficulties and irregularities. It is therefore of the greatest importance, both theoretical and practical, to demonstrate its dependability.

It was with this end in view that the studies here reported were undertaken. They are reported now, in preliminary form, because of the difference in results from those reported by Frank. Both series are far too small to give accurate evidence of the errors necessarily involved, and it is hoped that these discrepancies will stimulate others to undertake similar work and to report their results. Only by such accumulation of evidence will the true value of the test be established.

Since the inception of these studies, articles have appeared reporting the occurrence of similar reactions from extracts of sugar beets, potatoes, cherries and yeast,<sup>3</sup> and from the urine of males.<sup>4</sup> These

various observations must be checked up and their true importance established. On such evaluation, the blood test may still be found of great use in spite of the similarity of these other reactions. Studies are now under way with a view to determining the identity or difference of the various substances which have been reported to produce the vaginal smear reaction.

The technic at first in use in these tests was as nearly as possible that described by Frank and Goldberger.<sup>1</sup> During the course of the experiments it has seemed advisable to make certain technical changes, which will be discussed in detail.

The first change of note is in the number of control smears and the selection of the mice for injection. It became apparent rather early in the work that castrated mice, though their smears were all theoretically zero (Frank reading), actually showed nucleated and cornified epithelial cells in varying numbers. This must necessarily be so, for all epithelial tissues, even when cyclic changes do not occur, undergo surface desquamation to a greater or less degree. It has, therefore, been made a rule in this work to take control smears from the mice on the two days preceding injection and on the morning of injection. These smears taken on successive days, covering half the average estrus cycle of a mouse,<sup>2</sup> should determine without question whether a mouse which shows an uncertain smear on the first day is starting a spontaneous cycle or not. If an uncertain smear occurs as the second or third of the series, the mouse is not used. By this method, it is safe to use some mice that would otherwise have to be discarded as uncertain on the basis of a single smear.

In a few cases, mice have shown a continuous number four smear. According to Evans,<sup>3</sup> this is due to deficiency of vitamin A in the diet. My co-workers and I have arranged the diet in our animal colony to counteract such deficiencies, and have been successful in that only a very small proportion of our mice show this condition. It would seem that these few mice represent a threshold variation in their vitamin A requirement, for they do not occur more frequently than one or two in each hundred. We have watched them on different diets and taken smears over considerable periods without having been able to change the cytologic contents of the vagina; we now kill such mice when they appear.

During the course of the work there have been times when it has been necessary to keep blood specimens over for long periods before injection. Where these instances occurred with the original technic the blood was

kept under alcohol and in well stoppered bottles. Since the adoption of the sodium sulphate technic<sup>7</sup> for desiccation, such specimens are extracted with ether and the ether extracts stored in stoppered bottles. They have been kept away from light and are usually stored in the icebox. The experience with these older blood specimens has made it apparent that the residue of the ether extract emulsifies with more difficulty than that derived from fresh blood. Bicarbonate and carbonate of sodium have been used to help emulsification, and the latter has been found more effective. In some cases, even when the blood has not stood, the lipid has a buttery consistency, so that the addition of carbonate was necessary in order to bring about emulsification.

In the preliminary tabulations for this report, it was felt that the protracted storage of blood extracts before injection constituted a definite factor which could possibly produce a difference in the observed results owing to changes of a destructive nature that occurred in the hormone on standing. The separate tabulation of these two groups of cases has shown such close correspondence in the results that they have been consolidated for the tables here presented.

The desiccation process by the use of sodium sulphate has been changed by using larger amounts of the salt than those recommended in the modified technic.<sup>7</sup> Fifty grams of the salt to 40 cc. of blood are now used. During the summer, when the weather was humid, it was nearly always necessary to use more than that called for by the modified technic and on various occasions, after pulverization and extraction of the blood-sulphate mixture, the evaporated residue contained water carried over in the ether. This water probably contained sulphate in solution; when present, it was removed with solid sulphate and the material reextracted with ether. From a chemical standpoint, it is preferable to use an excess of sulphate rather than the reverse. Most chemical reactions take place in the presence of water or some other solvent, and if the solvent is removed the reaction is less rapid and less extensive, even in the presence of an excess of the reagents. Furthermore, excess of the solid phase is without influence from the standpoint of mass action.

Another technical difference may, in some measure, be responsible for the discrepancies between these results and those of Frank. In this work, it has been customary to centrifugate the ether extracts, after a rough decantation, to insure a final clear solution. It has been impossible otherwise to avoid contamination of the ether extract with some of the solid elements of the blood mixture. The amount of sediment thrown down is seldom more than 1 cc., and therefore any adsorption

---

7. Frank and Goldberger: *The Female Sex Hormone: Simplification of Technic*, J. A. M. A. 90:376 (Feb. 4) 1928.

of active follicular material on it must be minimal. Even at the risk of such loss, it was felt preferable to introduce this theoretical quantitative error rather than to risk qualitative errors of unknown variety and extent by the inclusion of proteins or other blood portions.

The reading of the smears has been according to the classification of Frank.<sup>1</sup> A number 2 smear is classed as doubtful, while 2 +, 3 and 4 are positive smears of different grades.

The material on which this report is based represents a total of 256 injections. The following deductions were made: 8 injections because of error in control smears, 5 blood extracts from pregnant and 6 from nonpregnant subjects because of insufficient data to classify

TABLE 1—*Material Used and Rejected in This Study*

2 catamenia	2	1	50	0	0	1	50

them properly, 2 from cases of menorrhagia, 2 from postpartum cases and, lastly, 30 injections because the mice died before showing a reaction. It will be noted here that animals which gave doubtful or positive reactions have been so classified even in case they subsequently died. We have followed Frank's custom of accepting smears made after death if the mouse is still warm. The foregoing cases represent all those deducted for any reason (table 1). The remaining unselected series of 203 cases represents the basis for the following conclusions.

Table 2 and chart 1 show in tabular and graphic form the list of nonpregnant cases. Comparison of this with Frank's figures shows discrepancies, which are most marked in the group comprised by the cases from one to three days premenstrual, although the whole trend of the curve is in an opposite sense to that of the latter.

Table 3 and chart 2 deal in a similar way with the blood from pregnant subjects. There is a closer correspondence with Frank's

Chart 1.—Nonpregnant cases.

Chart 2.—Pregnant cases. The dotted line represents the curve obtained by plotting positive and doubtful cases together.

observations in this table, the chief difference lying in the higher proportion of positive tests which he gets in the fifth, sixth and seventh months. In this series the figures show a tendency to drop at the ninth month rather than to rise. This may be due to the fact that the nine month group is so small. The results reported by Smith<sup>8</sup> in a group of pregnant cases correspond in a general way with table 3 and chart 2. In her report is shown a tremendous difference in the amount of blood necessary to produce a rat (or mouse) unit in any one month group. In this relation, the variations in the response to a rat or mouse unit, reported by Coward and Burn,<sup>9</sup> are of the greatest importance. They conclude as a result of their experiments that variations as high as 1,000 per cent exist between individual animals.

TABLE 3.—*Results of Ovarian Smear Reaction in Pregnant Subjects*

Month of Pregnancy	Total	Positive		Doubtful		Negative	
		Number	Percentage	Number	Percentage	Number	Percentage

7.....	3	2	66	1	33	0	0
8.....	15	12	80	3	20	0	0
9.....	8	6	75	0	0	2	25

TABLE 4.—*Results in Controls*

Total	Positive		Doubtful		Negative	
	Number	Percentage	Number	Percentage	Number	Percentage
9.....	0	0	1	11	8	89

Table 4 deals with the nine control injections. These blood specimens were obtained either from males or from castrated females. The one doubtful case recorded falls in the latter group.

No more definite conclusions seem warranted from such a small series of tests than that there is considerable variance between these results and those already reported. Neither one series nor the combination of them all to date is sufficiently large to determine accurately the reliability of the test. Much additional work is necessary before final conclusions may be reached. Work is being continued in this laboratory with the hope of reporting a larger series of tests in the future to add to the material already in hand.

# VIDIAN NEURALGIA FROM DISEASE OF THE SPHENOIDAL SINUS

REPORT OF A CASE

HARRIS H. VAIL

By 1908, reports of extensive anatomic studies of the nasal sinuses had been made by Zuckerkandl,<sup>1</sup> Grünwald,<sup>2</sup> Onodi<sup>3</sup> and Killian.<sup>4</sup> It was at this time that an American rhinologist, Dr. Greenfield Sluder,<sup>5</sup> published the first of his many important contributions to the anatomic, clinical, pathologic and therapeutic phases of disease of the posterior nasal sinuses and the nervous structure affected by it.

Since then, owing chiefly to Sluder's work, the sphenopalatine ganglion has become of great importance in the consideration of the neuralgias about the face. These neuralgias may be grouped in three main types: (1) the true trigeminal neuralgias, (2) the pseudotrigeminal neuralgias, and (3) the sphenopalatine and vidian neuralgias.

Many contributions to the knowledge of the first and second groups have come from the work of Dr. Harvey Cushing.

Sluder has done pioneer work in the matter of the sphenopalatine neuroses and vidian neuralgias. Judging from the scarcity of the reports of cases of vidian neuralgia, this type seems to be either rare or submerged in the larger group of the sphenopalatine neuralgias. Sluder<sup>6</sup> stated that experimentally he was able to produce by electrical stimulation to the vidian nerve in the sphenomaxillary fossa, pain in the ear, mastoid, occiput, neck, shoulder blade, shoulder, arm, forearm and hand, and used the term "vidian neuralgia" to describe such a distribution of pain. He also stated that the pain in the teeth, eye and temple was the anterior or maxillary part of the symptom-complex of Meckel's

ganglion neuralgia. He<sup>7</sup> reported several cases of vidian neuralgia and described tic of the vidian nerve as follows: "Sharp, recurrent, stabbing attacks of pain in the lower half of the head, in the neck and shoulder, at intervals of not more than a few hours apart."

In the consideration of vidian neuralgia, it is important to remember that the vidian canal may establish close anatomic relations with the sphenoidal sinus by the sixth or seventh year, but the closest relations between the vidian canal and the sphenoidal sinus are not made until about the fourteenth year.

Schaeffer,<sup>8</sup> Sluder,<sup>9</sup> Mosher,<sup>10</sup> Onodi,<sup>11</sup> Grünwald<sup>12</sup> and many others described the intimate relations between the sphenoidal sinus and the vidian nerve running in the vidian canal. This intimate relation is due chiefly to pneumatization of the pterygoid process and even the pterygoid plates.

Many anatomic preparations show the vidian canal running as a prominent ridge through the floor of the sphenoidal sinus with recesses or prolongations of the sinus, median and lateral to it. Dehiscences in the bony wall of the canal may place the sinus mucosa in direct contact with the nerve sheath.

The large type of sphenoidal sinus with recesses and prolongations is more subject to what has been termed latent sinusitis by Canuyt, Ramadier and Velter.<sup>13</sup> These authors feel that sphenoid sinusitis is a serious condition, without much tendency to spontaneous healing, particularly when there are prolongations extending deeply in the pterygoid plates or wings of the sphenoid. Lemaitre<sup>14</sup> stated "*Les sinusitis compliqués n'aiment pas les petits sinus.*"

13. Canuyt, Ramadier and Velter: Les sinusites posteurieuses et leur complications oculaires, *Ann. d. mal. de l'oreille, du larynx* 44:39 and 140 (Jan. and Feb.) 1925.

14. Lemaitre, F.: Les complications orbito-oculaires des sinusites, *Bull. et mém. Soc. franç. d'oto. rhino. laryng.* 34:59, 1921.

The two chief factors in the production of vidian neuralgia are (1) infection in the mucosa of a large sphenoid sinus, and (2) a thin bony wall of the vidian canal with or without dehiscences.

#### REPORT OF CASE

*History.*—H. B., a man, aged 29, was first seen June 10, 1925, referred by Dr. F. C. Theiss with the diagnosis of Meckel's ganglion neuralgia. The history was unimportant, except that his nose had been fractured in 1918. The present illness dated back to 1920, when he began to have paroxysms of pain which were severe, stabbing and continuous. The pain starting on the left side of the nose, just below the inner canthus, would radiate across the face into the left eyeball, forehead, upper teeth (with the exception of the incisors), palate, ear, neck and shoulder on the left side. The attacks of pain, coming at irregular intervals, would last from one to three hours. The longest period of freedom from the paroxysms

Fig. 1.—Anatomic preparation, obtained through the kindness of the Department of Laryngology of the Medical School of the University of Cincinnati, showing the close relationship of the vidian canal to the sphenoid sinus and the tendency for pneumatization of the pterygoid process. *A*, indicates vidian canal; *B*, pterygoid process.

was four months. Often, the attacks would be daily for a week or ten days. The pain appeared at any time of the day or night, though most frequently at midday. At times the attacks were suggestive of malaria. Not at any time during the attacks of pain had he noticed sneezing, nasal obstruction, rhinorrhea or nasal discharge. Visual or sensory disturbances had never been observed. External stimulation to the face or mouth had never provoked an attack.

Though he had nasal colds, the patient had never noticed any relation between them and the attacks of pain. He stated that he had had colds with pains and had had pains without being aware of having a cold in his head. On the cessation of an attack, his only after-symptom was a worn out feeling.

Two intranasal operations done in 1922 and 1923 did not give relief, and he stated that every physician he consulted had diagnosed his case as Meckel's ganglion neuralgia.

Rhinologic examination showed a deviation of the nasal septum to the right. A partial anterior resection of the septum had been performed, as well as an operation on the anterior ethmoid on the left side. The left middle turbinal was rather large and in close contact with the septum, preventing a view of the anterior wall of the sphenoidal sinus. Pus or secretions could not be seen.

There was not any sensory disturbance of the face.

Results of the general physical, neurologic and serologic examinations were negative.

The patient was seen at irregular intervals during the summer of 1925, but not at any time during an attack, in spite of the fact that he was having many severe

Fig. 2.—Photograph of figure 195 in Schaeffer's textbook (Schaeffer, J. P.: *The Nose, Paranasal Sinuses, Nasolacrimal Passageways and Olfactory Organ in Man*, Philadelphia, P. Blakiston's Sons & Company, 1920). This preparation by Dr. Schaeffer shows particularly well the anatomic relationships between the sphenoid sinus and the vidian nerve, in addition to the other important relationships.

ones. On one occasion, he was seen as a severe attack was subsiding, and, after nine minutes of application of cocaine flakes and epinephrine hydrochloride to the region of the sphenopalatine foramen, the pain disappeared.

During the winter of 1925, he was fairly comfortable in spite of the fact that he had had a nasal cold all this time. The attacks of pain returned early in February, 1926. At this time, roentgen examination showed an increase of density in the region of the left posterior ethmoid. The remaining sinuses were

Fig. 3.—X-ray film showing a lateral view of the left sphenoidal sinus of the patient in the case reported in this article. Note the large size of the sphenoid sinus

Fig. 4.—X-ray film which shows on the left side the sphenoid sinuses, as demonstrated by projection of x-rays through the open mouth. On the right side is the Granger angle, with the outline of the sphenoid sinus touched up to accentuate the size of the right and left sphenoidal sinus.

clear. The left sphenoidal sinus was large, approximately three times the size of the right one, with the intersphenoidal septum to the right of the midline.

*Operation.*—On March 17, 1926, under local anesthesia, a submucous resection of the nasal septum was carried to the front wall of the sphenoid. This procedure, along with the removal of the anterior half of the left middle turbinal, permitted a good exposure of the front wall of the sphenoidal sinus. The left sphenoidal sinus was then opened. The Holmes nasopharyngoscope was passed into the sphenoid sinus, and the interior of the cavity was inspected through it. Pathologic changes were not seen. However, two funnel-shaped recesses leading downward and outward were seen in the floor of the sphenoid sinus. Between these two openings, which seemed to be about 1 cm. in their long axis, there was a narrow ridge projecting well above their level. The ridge ran in an anterior and posterior direction. The mucosa lying over the ridge was yellowish, whereas, elsewhere in the sinus it was of the usual grayish appearance. This was the ridge of the vidian canal with a bony wall so thin that it allowed the yellow color of the vidian nerve to be transmitted through it.

The left posterior and anterior ethmoid cells were opened. Pus was evacuated from the bulla ethmoidalis.

Fig. 5.—Side view of the specimen as shown in figure 1. It shows well the view obtained by the Holmes nasopharyngoscope inserted into the cavity of the sphenoid. The ridge formed by the vidian canal with pterygoid recesses can be well seen.

During his postoperative course, the patient passed through a severe bilateral maxillary sinusitis and otitis media without the recurrence of the neuralgia pains, and by July, 1926, he had entirely recovered.

He returned on March 12, 1927, stating that aside from a few mild attacks during February, 1927, he had had complete relief.

Three days later, wishing to show the patient before the Cincinnati Academy of Medicine, I asked him to return, as I desired to demonstrate the size and the pterygoid recesses of the sphenoidal sinus by the injection of iodized oil 40 per cent into the sinus.

While 10 cc. of iodized oil 40 per cent was being injected through the operative opening in the front wall of the sphenoid, the patient stated that an attack was induced. The attack was of typical onset and distribution, but was mild and lasted about two minutes. He complained about pain in his left eye, and a remarkable phenomenon was discovered. The left pupil became sharply contracted and was battered in contour. The conjunctiva suddenly became reddened. The right eye was entirely normal. Roentgen examination of the sphenoidal sinuses was made soon after. Unfortunately, the prolongations into the pterygoid region were not filled with the iodized oil, though sufficient remained in the sinus to show its large size.

Two days later, the patient was presented at the Cincinnati Academy of Medicine, and for possibly half an hour the nasopharyngoscope was allowed to remain in the sphenoid sinus.

Four days after this, he returned on account of the recurrence of the attacks of pain, which for the most part had been quite severe. Examination of the sphenoidal sinus by means of the nasopharyngoscope showed a marked pathology in its cavity. The openings in the recesses in the floor were closed by edema. In fact, there was so much edema of the mucosa in the region of the more medial recess that it resembled a polyp formation. In addition to the edema, congestion of the sinus mucosa with many blood vessels was seen where previously none had been noticed.

For the two weeks following, the patient had many severe attacks of pain, similar in every respect to those prior to the operation. Only slight relief was

Fig. 6.—Lateral view of the sphenoidal sinus after injection with iodized oil 40 per cent. The large size of the sphenoidal sinus is well shown. It is impossible to demonstrate any filling of the pterygoid processes.

obtained by the injection of solutions of cocaine into the sinus. When the edema and congestion of the sinus mucosa cleared up, the attacks of pain ceased.

During December, 1927, the patient noticed mild recurrent attacks, and when I saw him as I did the day following such attacks, a slight amount of edema was always found in the region of the downward prolongation.

In February, 1928, the patient contracted a cold in the nose. The attacks of pain returned and were severe for a month. Examination revealed pus escaping from the operative opening of the sphenoidal sinus, and so much edema of the mucous membrane was seen with the nasopharyngoscope that it was impossible to obtain a view of the recesses. Pus could be seen issuing from the region of the more lateral of the recesses. In addition to the sphenoiditis, there was a left maxillary sinusitis. This latter required several antral lavages before it cleared up. Under daily treatment of the sphenoid sinus (irrigations, instillations of

mild silver protein, infra-red light therapy, etc.), the congestion cleared up, and by the last of February, 1928, the pathologic state of the mucosa had disappeared.

The patient was last seen on Sept. 15, 1928, when he stated that he had not had any pain for six months.

#### SUMMARY OF CASE

The chief points of interest in this case are:

1. Neuralgic pains similar to those assigned to Meckel's ganglion neuralgia were present.

2. Observation over a period of three years showed that a sphenoiditis was always present with the neuralgia.

3. An operative opening of the sphenoidal sinus made it possible, by means of the nasopharyngoscope, to see plainly the size of the sinus and the nature of the disease present in it. In addition, the ridge of the vidian canal between a median and a lateral pterygoid recess or prolongation could be seen. The bony wall of the vidian canal was thin, permitting the yellowish color of the vidian nerve to shine through it.

4. At the moment of injection of iodized oil 40 per cent into the sphenoid sinus for roentgen diagnostic purposes, an attack of neuralgia, similar in distribution to previous attacks, was induced. A most remarkable phenomenon was observed, namely, a contraction and irregularity in contour of the pupil on that side, with reddening of the conjunctiva during the few minutes the attack lasted.

5. Within six days following the injection of iodized oil 40 per cent, the appearance of the sphenoidal mucosa had changed from a perfectly healthy looking membrane into a markedly congested and swollen one, completely obscuring the recesses. And during the time that these changes lasted, the patient had many severe attacks of neuralgic pain, similar in every respect to previous attacks.

6. At a later date, with each recurrence of neuralgic pains, the sphenoidal sinus mucosa showed the same inflammatory reactions with pus to be seen issuing from the depth of one of the recesses.

#### COMMENT

Infection may be present in a sphenoidal sinus without the patients being aware of it by any subjective symptoms, such as are usually assigned to cold in the nose. During the attacks of pain, this patient was rarely aware that he was having a cold, and yet examination of the sphenoidal sinus by the nasopharyngoscope invariably showed the signs of infection.

Every patient with neuralgic pain in the face should receive the benefit of a complete examination of the nasal sinuses. In order to do this I propose to make an opening into the sphenoidal sinus for the purpose of inspecting the cavity, if the roentgen examination shows

the sinus to be of large size. This, after all, is not any more dangerous to the patient than an exploratory puncture for the purpose of irrigation. The benefits derived from the surgical exploration of the sphenoidal sinus are greater than those derived from puncture of the anterior wall or lavage through the ostium; it enables one in most cases to study the intramural structure of the sinus. My feeling is that this procedure will demonstrate that many cases thought to be Meckel's ganglion neuralgia are vidian neuralgia.

Local treatments to the sphenopalatine ganglion may afford temporary relief, but one may, by delay in getting at the underlying condition, allow the patient to pass over into the *tic douloureux* stage.

It may be possible to find in the sphenoidal sinus the etiologic factor of some of the cases of *tic douloureux*, though, of course, by the time the patient reaches the condition in which the neurosurgeon finds him, nothing but procedures directed to the gasserian ganglion will afford relief.

The size and the relations of the sphenoidal sinus cannot be altered by the operative procedure, but by operation one not only accomplishes aeration and drainage of the sinus, but gains an opportunity to see the disease in the sinus and to medicate the infection of the sinus in the cases of recurrent attacks.

#### CONCLUSIONS

A case is reported with symptoms hitherto ascribed to Meckel's ganglion neuralgia, which were demonstrated to be due to vidian neuralgia, the result of an infection in an extensively pneumatized sphenoidal sinus.

Stimulation of the vidian nerve in its canal by means of the injection of iodized oil 40 per cent caused an attack of pain located not only in the typical distribution of vidian neuralgia, as described by Sluder, but also in the region hitherto ascribed to the anterior or maxillary part of the syndrome, namely, pain in the eyeball, a contraction of the pupil with irregularity of its contour, reddening of the conjunctiva and pain in the upper canine, bicuspid and molar teeth.

The case reported seems to show that it may be possible for the painful symptoms assigned to Meckel's ganglion neurosis to be relieved by treatment directed to the sphenoid disease, without any treatment directed to the sphenopalatine ganglion itself.

# THE TEACHING OF UROLOGY IN THE SURGICAL CURRICULUM

WILLIAM C. QUINBY

The time passed about eighteen years ago when the question of whether urology was entitled to be a specialty within the domain of surgery could be seriously discussed in the form of a presidential address before the American Urological Association. The definition of a specialty was that it was "a department of medicine in which our knowledge has become so far developed that it requires the whole time of any individual to keep abreast of the accumulating knowledge and still have time to devote to study of the problems presented." That even in 1911 urology was entitled to be considered a specialty was the conclusion both of the essayist and of those taking part in the discussion of the paper. Today there is no doubt that this decision was in accord with the truth, and were proof needed, one has but to consider the subsequent widespread development of men and departments devoted to the study and treatment of diseases of the genito-urinary organs in the outstanding schools and hospitals. The American Association of Genito-Urinary Surgeons today has sixty-six members; in 1910, there were fifty-one members. The American Urological Association has a membership of 804 persons. Each association holds an annual meeting, and the national society also meets once in three years as a member of the Congress of American Physicians and Surgeons. Also a section of the American Medical Association is devoted to urology, and its program contains many valuable titles each year. An International Congress of Urology is held at intervals three years apart, at which America is well represented. There are two journals in the English language devoted to this specialty alone, and a third is even now about to make its appearance. A similar rapid increase in the development of many other fields within the domain of surgery has also occurred within the last quinquennium; as, for instance, in orthopedics or in the surgery of the nervous system.

Manifestly, such a sum of detailed information cannot be offered a student of surgery in his already well crowded curriculum without unjustly burdening him to the point of confusion. One, therefore, does well to ask how much and what portions of urology should appear in the course in surgery as a prerequisite to the degree of Doctor of Medicine.

The decision in this regard will depend, in large measure, I feel, on the following facts: First, it should always be the aim in undergraduate medical teaching to offer the student a training in the broad aspects of

general medicine and general surgery firmly based on a knowledge of the fundamental facts of physiology and pathology. Second, because the diseases with which urology is concerned have many borderline aspects between both medicine and surgery, this intimate relation between the specialty and the more general subjects should be emphasized continuously. Also, since many of the diseases of interest to the urologist are either local manifestations of a general process or pathologic states affecting in turn different portions of the urinary and genital tracts, instruction should concern the life history of such diseases as a whole rather than be given under anatomic headings.

A condensed tabular view of the information which every medical student should acquire before graduation is as follows:

1. Urologic Examination and Diagnostic Methods
  - (a) The examination of the urine
  - (b) Instruments
  - (c) Asepsis
  - (d) Examination of testes, urethra, prostate and vesicles, bladder, ureters and kidney pelves, kidney
  - (e) The x-rays in urologic diagnosis
  - (f) Renal function tests
2. Physiology of the Urogenital Organs
  - (a) Interrelations of heart, kidney and bladder
  - (b) Micturition
  - (c) Function of the renal pelvis and ureter
  - (d) Function of the kidney
  - (e) Function of the testis and accessory genital glands
3. Pathologic Physiology of the Urogenital Organs
  - (a) Retention of urine
  - (b) Incontinence of urine
  - (c) Polyuria
  - (d) Anuria
4. Embryology of the Genito-Urinary Organs and the Clinical Significance of Developmental Anomalies
  - (a) Displacements and acquired deformities
5. Infections of the Urogenital Tract
  - (a) Their relation to infections of the body in general
  - (b) Their local manifestations in kidney, bladder, prostate and urethra
6. Tuberculosis of the Urogenital Tract
7. Infestations by Parasites
8. Lithiasis and Its Complications
9. Tumors of the Genito-Urinary Organs
  - (a) Hypertrophy of the prostate
10. Trauma and Foreign Bodies

Were the whole of the foregoing outline to be presented to the student as a didactic course of lectures there would ensue much repetition and loss of time. Furthermore, the didactic lecture had in most

instances far better be replaced by the clinic, leaving any omissions to be covered by outside reading. Thus the subjects noted under the first four headings will be taught at various times and by various instructors during the first two years of medical school work as a part of the courses in general diagnosis, physiology and pathology. To this will be added, usually during the third year, practice in the actual performance of diagnostic procedures. This instruction must be largely to the individual student or to very small groups, and is most conveniently carried out in the ambulatory clinic. So far as the rather extensive armamentarium of the urologist is concerned, only those measures which apply to diagnosis and simple treatment should be stressed. The use of the cystoscope, therefore, can be taught the pupil in an analogous manner and even at the same time in his career as he is instructed in the ophthalmoscope or the laryngoscope. Here also, the various manifestations of gonorrhea will be taught.

During the third or fourth year, the class as a whole should attend a sufficient number of lecture-clinics to have clearly presented to them such subjects as the significance of hematuria and pyuria, hypertrophy of the prostate and other forms of abnormality of urination, infections in general, tuberculosis and neoplasms.

It may seem by comparison with the mass of information available that these requirements are meager. When compared, however, with the aggregate amount of knowledge comprised today under the heading of surgery, it will more readily be seen that the ratio is a fair one, for one must keep constantly in mind the fact that it is a point of view concerning medical and surgical diseases as a whole which should be demanded of the student; not that he should become a specialist. Furthermore, no worker in any one special field has the right to assume that because he is deeply interested in his subject, the student must also take an equally active interest in it.

Should the student wish to acquire a more intimate knowledge of urology, the time to obtain this is as a resident in hospital after he has finished his internship in general surgery. In such a post, he will be able to devote himself entirely to the group of diseases comprised by urology at a time when he will have acquired sufficient maturity to profit by such experience.

# CHOLECYSTOTOMY VERSUS CHOLECYSTECTOMY\*

LOUIS F. FALLON

The general practitioner who also performs operations is likely to develop a different attitude toward his cases, perhaps because his errors of judgment are always with him. It is customary for the specialist-surgeon to return the patient to the care of his regular physician when the operative convalescence is complete. If the operation is not completely successful or if there is recurrence of the trouble, it is thus the general physician who frequently shoulders the worry and discouragement. When a single person shoulders both jobs, that of the surgeon and that of the practitioner, it is certain that the patient will know whom to blame.

Cholelithiasis is a condition in which operation not infrequently proves disappointing. Fortunately, this experience seems to be decreasing, and this decrease probably is in relation to the growing tendency to practice removal of the gallbladder. It is because of the disappointments in my own practice that this paper is written.

These fourteen consecutive cases are presented with the hope that they will bring out some points of value in this relation. As a rule, one is apt to look for the classic symptoms of disease of the gallbladder, i. e., typical attacks of gallstone colic with or without jaundice, before one ventures the diagnosis of gallbladder disease.

## REPORT OF CASES

I shall briefly review the essential points in each case.

CASE 1.—Mrs. E. P. gave a history of sharp attacks of pain in the epigastrium at frequent intervals. She suffered considerably from "indigestion," as evidenced by a burning pain after eating and gaseous eructations. When she was first seen three years before operation, gallstones were considered the probable cause of her trouble, but she refused operation. When she returned again she had constant aching pain, which was worse after eating, and she had lost weight. Malignant disease was now considered. At operation the gallbladder, with five large stones, was removed. The gallbladder was much thickened, but there was no evidence of malignant disease. The patient made an uneventful recovery, and when last heard from was enjoying better health than she had had for many years.

CASE 2.—Mrs. E. T. had suffered for a long period with "indigestion" which culminated recently in a rather typical attack of gallstone colic associated with jaundice. In this case, the gallbladder was drained after removal of the stones. The patient made a prolonged though uneventful recovery. She left the country

---

\* From Clinical Work, St. Clau's Mercy Hospital, St. Johns, Newfoundland.

\* Read before the St. Johns Clinical Society, St. Johns, Newfoundland, December, 1927.

shortly after the operation, and while a direct communication has not been received, it is understood that there has been a recurrence.

CASE 3.—Mrs. E. C. gave a history of typical gallstone colic, the attacks being more frequent after confinements. Between attacks she suffered from gastric discomfort, which consisted of burning after eating and gaseous eructations. A cholecystectomy was done. The patient made an excellent and rapid recovery, and has enjoyed good health ever since.

CASE 4.—Mrs. M. D., aged 27, had typical attacks of gallstone colic, one attack occurring with jaundice. Cholecystectomy was performed three years ago. She is beginning to have recurrent symptoms, and I regret not having removed the gallbladder.

CASE 5.—Mrs. C. H. suffered mostly with attacks of sharp pain in the epigastrium. The pain did not seem to radiate and was not accompanied at any time with jaundice. Cholecystectomy was performed two years ago, and she has enjoyed excellent health ever since.

CASE 6.—Mrs. M., aged 66, for years suffered from "indigestion" which seemed to consist of burning or gnawing pain in the epigastrium and gaseous eructations. Later, she developed sharp attacks of typical pain which several times was accompanied with jaundice. Cholecystectomy was performed, and for the past two years she has really enjoyed life.

CASE 7.—Mrs. M. T., aged 46, had a severe attack of pain and jaundice. During the succeeding year, she suffered with a gnawing in her stomach and gaseous eructations. The Graham test indicated cholecystitis. At operation there were no stones, but the omentum was adherent to the gallbladder, which was thickened. The gallbladder was removed. The patient's general health and gastric condition have been improved since the operation.

CASE 8.—Mrs. A. S. had a previous cholecystectomy done by another surgeon seven years before I saw her. The trouble at the time of examination was mostly dull pain and discomfort after eating, the pain becoming acute at times. She had not been jaundiced since her last operation. The Graham test showed a mottling indicative of stones. The operation was difficult because of the dense adhesions from the former operation. The gallbladder was found to contain stones and was removed. The condition for which the patient sought relief has cleared up.

CASE 9.—In Mrs. H. W., aged 40, the attacks were fairly typical. She also had attacks of jaundice. The Graham test indicated stones. At operation, the gallbladder was found full of stones and was removed. This patient was the sister of the patient in case 5.

CASE 10.—I had performed a cholecystectomy on Mrs. F. C. two years before for rather typical attacks of colic, but she was never jaundiced. The Graham test indicated stones, which were found at the second operation. The gallbladder was removed, and the patient now seems in good health.

CASE 11.—Mrs. W., aged 55, had for years suffered pain after eating, considerable gaseous eructations and vomiting at times, with relief. There had been loss of weight, and the patient appeared cachectic. Roentgen examination of the gastro-intestinal tract gave negative results, except for a poorly stained gallbladder which suggested cholecystitis. The operation was in the nature of an exploratory one with the expectation of finding a malignant condition following ulceration. At operation tumor or ulcer sites could not be found, but the gallbladder was considerably distended with several adhesions to the transverse colon and omentum. The gallbladder was removed, and at the end of a year the patient

stated that she was enjoying life more than she had for twenty years. She had put on weight and was almost entirely free from gastric distress.

CASE 12.—Mrs. W., aged 46, entered the hospital for gynecologic examination. The history elicited the fact that for many years she had suffered from gastric discomfort consisting of burning pain in the epigastrium which grew worse after eating, and gaseous eructations. She never had attacks indicative of colic nor had she ever been jaundiced. There was tenderness over the gallbladder. The Graham test indicated stones. This was confirmed at operation, and the gallbladder was removed.

CASE 13.—Mrs. B. gave a history of colic but no jaundice. The Graham test indicated stones. This was confirmed at operation, and the gallbladder was removed.

CASE 14.—Mrs. L. was admitted to the hospital because of lower abdominal distress. There was a history of considerable indigestion at times, which consisted of gnawing in the epigastrium and gaseous eructations. There were never any attacks indicative of colic, nor was she ever jaundiced. An operation was performed for lower abdominal disease, and a small ovarian cyst and the appendix were removed. In the course of exploration, the gallbladder was found to contain stones. It was small and nonfunctioning and was excised. The patient has been in good health since the operation. Whether the gallbladder was responsible for the condition I cannot say, but I believe it highly probable.

I realize that it is ridiculous to draw positive conclusions from so small a group, but this study does point the way to thoughts that are more or less borne out by others with a much larger experience. Only 43 per cent of this group had ever been jaundiced. While 75 per cent had attacks of sharp pain strongly indicative of gallstone colic, they went for varying periods of years with an indefinite history of indigestion.

The familial tendency in this small group is striking. In one family two sisters were affected, and their mother has had definite attacks of gallstone colic, although as yet she has not come to operation. Another sister is showing suspicious signs of indigestion. I recall another family with a similar history. Is there a hereditary predisposition toward the precipitation of bile salts or is there a hereditary predisposition for the selective action of bacteria? In none of these cases was there a history of typhoid fever.

It is a well recognized observation that gallstones are more prevalent in women, especially in those who have borne children. The first attacks of colic frequently come on just after the puerperium.

The fact that so many of these cases showed years of indefinite indigestion has convinced me that one should study all cases of indefinite and obstinate indigestion from the standpoint of possible disease of the gallbladder. Here the x-rays and the Graham test may be of considerable help. The general experience seems to be that the Graham test is reliable in about 9 per cent of its reports. It does not supplant clinical observation, nor should it be accepted *per se*; however, it is a valuable adjuvant in arriving at a diagnosis.

## CONCLUSIONS

My main object in this discussion is to determine whether cholecystectomy is not a more desirable operation than simple drainage. Before I state the reasons why it seems more desirable, it would be well to consider what are the accepted functions of the gallbladder. The only definite function that all agree on is that of storage of bile. In addition, it is suggested by some that considerable mucus is secreted which is necessary in the dilution of the bile. However, it is generally known that a great many people who have parted with their gallbladders are not only living, but are considerably improved by the operation. The gallbladder does not seem to be necessary to life.

My reasons for believing that cholecystectomy is the operation of choice are:

1. A diseased gallbladder nearly always remains diseased.

2. Various authorities state that gallstones recur in from 30 to 60 per cent of the cases in which simple drainage alone has been resorted to. In other words, a large percentage of patients come back for operation sooner or later.

3. When a patient comes to reoperation it is my experience to find dense adhesions, and the operation of removal becomes much more complicated and serious.

4. Gallstones are not a disease in themselves, but only a symptom of disease, and by removing the stones alone one is removing only a symptom and not the disease.

5. In cholecystectomy the raw surface can nearly always be covered over with the reflected peritoneum, and adhesions are less likely to form.

6. Convalescence is greatly shortened.

Disease of the gallbladder is frequently difficult to diagnose early, because the classic symptoms of colic and jaundice may not have been present, and the symptoms are indefinite.

The present dye-x-ray method of Graham is of considerable help in arriving at a diagnosis.

Cholecystectomy is the operation of choice if there are no definite contraindications.

# NEPHROLYSIS, URETEROLYSIS AND NEPHROPEXY

## AN ANALYSIS OF THIRTY CONSECUTIVE OPERATIONS WITH DESCRIPTION OF TECHNIC

VINCENT J. O'CONOR

There is probably no subject in medical literature which has given rise to such extreme divergence of opinion as the relative importance of abnormal renal mobility as an etiologic factor in the production of lumbar, abdominal and pelvic pain.

In more recent years, the association of faulty ureteral or renal pelvic drainage with the persistence or recurrence of renal infection, the formation of calculi and the development of hydronephrosis has furnished additional study and controversy among those most interested in these subjects.

With the marked improvement in modern methods of urologic diagnosis, notably the procedure of clearly outlining the ureter and renal pelvis with opaque material in the roentgenogram, it might seem that sufficiently accurate data could be obtained to decide whether or not, in a carefully studied patient, abnormal renal mobility actually resulted in distressing or damaging sequelae.

On the contrary, additional information of obstructive processes in and about the ureteral lumen has complicated the diagnostic picture until the subject of movable kidney cannot be considered apart from such lesions as are tabulated under the headings of ureteral stricture, ureteral kinks, angulation of the ureter, renal torsion and early hydronephrosis. Furthermore, the interpretation of ureteropyelogram, by the most experienced observers varies so greatly that when the various opinions are correlated with the idea of fairly analyzing the diagnostic and therapeutic problems of ureteral obstruction, whatever the underlying cause may be, one finds himself obliged to turn to an analysis of personal experience to arrive at a satisfactory conclusion.

In the light of these more modern methods of urologic diagnosis, it has been interesting to note that surgeons with a primary interest in surgical procedures on the urinary tract have gradually come to a new recognition of the value of operative measures which would free the kidney and ureter and restore pelvic and ureteral drainage by proper fixation of the kidney itself. The indications for such operative intervention in these instances are based on the accurate observation of urologic data and not on the ordinary physical symptoms which formerly led to unnecessary surgical procedures and a resultant widespread repudiation of so-called nephropexy or kidney fixation.

Kelly,<sup>1</sup> Burford,<sup>2</sup> Mathe,<sup>3</sup> Fowler, and others in this country, have recently reported in detail their successful treatment of persons with "ptosis" of the kidney. In their patients, accurate urographic observations confirmed the indications for operation. Kolischer<sup>4</sup> has emphasized the value of nephrolysis and ureterolysis, as first described by Rovsing, with similar effect in his patients.

The constantly increasing number of reports by leading urologists, both at home and abroad, support the fact that, in carefully studied cases, a suitable technic for freeing and fixing the kidney is followed by a highly satisfactory result which could not be obtained by other therapeutic procedures.

The occasion of this report necessitates a brevity which precludes an extensive resumé of the literature and any attempt at detailed study of individual case reports. The roentgenographic data and follow-up analysis, which is complete in each instance, will be limited to a few illustrations and a generalized summary.

This contribution is based on a careful study of thirty consecutive operations for the relief of malposition of the kidney and ureter, associated with faulty drainage, persistent urinary infection or early hydronephrosis, and clinically manifested by lumbar, abdominal or pelvic pain with or without objective or subjective symptoms referable to the urinary tract.

#### INCIDENCE

In 1,118 routine hospital urologic examinations conducted to determine the possibility of a pathologic process in the upper urinary tract, the diagnosis of abnormal mobility of the kidney was recorded in sixty-seven patients, sixty-three of whom were females and four males. The clinical situation prompted advice for operative intervention in forty-one of these persons. Thirty accepted operation; six are still under observation, and five did not return for further advice. Of the six still under my care, four have had no relief from nonoperative therapy and two are partially improved after complete progressive dilatation of the ureter.

Of the thirty patients on whom nephrolysis, ureterolysis and nephropexy was performed by the technic to be described, twenty-nine were females and one a male.<sup>5</sup> The only point of interest as to etiology

5. H. H. Young states that in 12,000 males admitted to the Brady Clinic, nephropexy was performed ten times with relief.

was that nine of the patients dated the onset and course of their trouble so intimately with mechanical injury, and the operative observations so closely tallied with this supposition, that they have been definitely classed as traumatic in origin. One cannot, of course, overlook the fact that in these persons there were undoubtedly predisposing factors which made this traumatic displacement possible. In this regard it is interesting to note that Kelly found a history of injury in only thirteen of 242 cases diagnosed as movable kidney causing clinical symptoms.

Of the thirty patients on whom operation was performed, the right kidney was displaced in twenty-six, the left in one (definite trauma), and was bilateral in three (one definitely traumatic in origin). Eighteen patients had infection of the affected kidney, and fourteen of these had been treated previously by removal of foci of infection, renal lavage and ureteral dilatation. In twenty-two patients, ureteral dilatation and conservative measures were carried out by me for periods of from six months to three years without obtaining permanent relief of pain or urinary infection when present. Sixteen of these patients had been operated on previously for the complaint cited at the time they first came under my observation. In no instance had relief been obtained. In eleven, the appendix had been removed; in three, operation for fixation of the uterus had been done and two had had explorations of the gallbladder without removal.

#### METHOD OF DIAGNOSIS

Ureteral catheterization with complete analytic and bacteriologic examination of the divided urine was performed in every instance, in addition to pyelo-ureterography in both the prone and the upright positions. Since the work of Goldstein<sup>6</sup> on fractional ureterography, twelve of these patients have had careful studies as to the emptying time of the pelvis and ureter. I consider this additional information as of great aid in deciding whether pelvic or ureteral stasis should be relieved by ureteral dilatation alone, operation alone, or combined dilatation and operation. In the twelve so studied, the pelvis showed an emptying time of from thirteen to sixty-six minutes. The normally draining ureter and pelvis is usually emptied of opaque material in from six to eight minutes. A retention after ten minutes is considered definitely abnormal. The patient is kept in the upright position during these observations.

The tip of the ureteral catheter was always kept in the lower ureter during the instillation of the opaque solution (12.5 per cent sodium iodide) and was then completely removed while fractional ureteropyelograms were being made.

---

6. Goldstein, A. E.: Scientific Study of the Normal Human Ureter by Fractional Uretero-Pyelography, *J. Urol.* 6:125 (July) 1921.

From my observations of these patients, both roentgenologic and anatomic, I am inclined to believe that ptosis of the kidney in itself is merely a contributory factor in the development of ureteral and pelvic stasis. When there are no abnormal peripelvic or peri-ureteral attachments or adhesions, the free course of pelvic or ureteral drainage seems rarely interrupted. But when sclerotic adhesions or posterior peritoneal attachments result in compression or angulation of the ureter in its

Fig. 1.—Method of capsule-reflection and the manner of placing tension-sutures through all three layers.

course from the pelvis to the bladder, the descent or rotation of the kidney results in obstruction and angulation at these areas. These observations are frequently, but not always, confirmed at operation, if great care is taken in the process of freeing the pelvis and ureter from their surrounding attachments. I believe it is for this reason that ureteral dilatation by bougies introduced within the lumen of the ureter gives only temporary, if any, relief of the obstruction in this type of pathologic condition.

The technic of operation, therefore, not only must include a proper replacement of the kidney in as nearly the normal position as possible, but also must provide for a complete freeing of the kidney, kidney-pelvis and ureter from surrounding attachments before the restoration of position is attempted.

Of the thirty patients operated on, abnormal peri-ureteral or pelvic attachments were demonstrated in sixteen. In six, there was a persistent lobulation of the kidney and in eight an anomalous or bipolar

Fig. 2.—Character of incision and method of freeing the ureter and kidney pelvis.

blood supply. In none of the latter instances was there ureteral or pelvic compression from the anomalous vessels such as is frequently seen in more marked hydronephroses. In two instances, there was a complete reduplication of the pelves and ureters.

The surgical technic adopted in these cases combines complete ureterolysis and nephrolysis (freeing of kidney and ureter) and suspension or fixation by a method which I have found to insure most satisfactorily a high fixation of the kidney. An incision (figs. 1, 2 and 3) is made just below and paralleling the anterior half of the twelfth

rib. It is then carried downward and forward and need not exceed 5 inches (12.7 cm.) in length. The kidney is freed in the usual manner, and all fatty tissue about the kidney and in the renal fossa is excised. The pelvis and ureter are carefully separated from all surrounding attachments, the latter being isolated down to the bifurcation of the iliac vessels. The kidney is completely freed so that the pedicle can also be isolated from any adherent structures. The true capsule is then incised both anteriorly and posteriorly at the upper pole and reflected carefully down to the region of the hilum. If this is done gently, cortical tissue will not be torn off with the capsule. The lower pole capsule is incised and reflected upward in a similar manner. This leaves a band of true capsule about 2 inches (5 cm.) wide surrounding the middle third of the kidney. The capsular layers are then overlapped

Fig. 3—Diagrammatic representation of position of kidney after the tension sutures have been tied above the twelfth rib.

so that three thicknesses are available for the placing of suspension sutures. A U-shaped interlocking continuous suture of no. 2 chromic catgut is then placed through the three capsular layers from the convexity toward the hilum, both anteriorly and posteriorly. The ends of these sutures are left from 6 to 8 inches (15.24 to 20.3 cm.) long, so that they may be easily carried above the exposed portion of the twelfth rib. The strength of these suspending ligatures when placed in this manner is great, and they can be tested by traction to show that no separation of capsule will result when they are placed under tension. The kidney is then displaced downward in the wound, and the renal fossa is enlarged by blunt stretching with moist gauze packs. The posterior tension sutures are then first carried under and above the twelfth rib as far toward the costovertebral angle as possible. When these are in place, the anterior sutures are also carried under and above

the twelfth rib 1 or 2 inches (2.5 or 5 cm.) in front of the sutures from the posterior side of the kidney. The kidney is then pushed up firmly beneath the diaphragm and the elevation apparatus on the table is lowered. While the kidney is held in position, the sutures are pulled up firmly and tied simultaneously above the rib. The remaining strands of all four are again tied. This procedure serves to hold the partially decapsulated kidney in such a position that adhesions to the psoas muscle and diaphragm are inevitable. The suspending sutures are merely temporary insurance that the kidney will be held in a proper high position while adhesions are being formed. No further "anchoring" of the kidney is necessary, and the usual closure can be made without drainage.

Fig. 4—*A* is a pyelo-ureterogram taken in a prone position; *B*, the same in an upright position showing marked ptosis, angulation of ureter, and early hydronephrosis, June, 1924; emptying time of the pelvis, eighteen minutes. *C* is taken in an upright position four years after operation showing normal pyelo-ureterogram and an emptying time of four minutes.

No elevation of the foot of the bed as a postoperative postural aid was used in this series. All patients were allowed to sit up in bed on the fourteenth postoperative day and to walk about without belts or corsets as soon after this time as their general condition warranted. Each one of the thirty patients walked out of the hospital in from sixteen to twenty days after operation.

#### CLINICAL RESULTS

Twenty-two of these patients have been seen and examined by me since June 1, 1928. Since Jan. 1, 1928, the remaining eight have written

Fig 5.—*A* is a pyelo-ureterogram taken in a prone position; *B*, the same in an upright position showing marked ptosis, angulation of ureter, January, 1925; *C*, upright position three years after operation showing normal pyelo-ureterogram and an emptying time of five minutes.

Fig. 6.—*A* is a pyelo-ureterogram taken in a prone position; *B*, the same in an upright position showing marked ptosis, rotation of kidney; emptying time, fifteen minutes, June, 1926. *C* is taken in an upright position showing a normal pelvis, decrease in hydronephrosis, broad ureteral kink, but an emptying time three and one-half minutes, June, 1928.

me, or their physicians have reported their progress. The duration since operation is as follows:

8 years .....	2 patients
7 years .....	4 patients
6 years .....	3 patients
5 years .....	5 patients
4 years .....	6 patients
3 years .....	4 patients
2 years .....	4 patients
1 year .....	2 patients

Symptomatically, these patients classify their results as follows: completely well, twenty-one patients; greatly improved, six; somewhat improved, two; not improved, one. (The patient last mentioned was one with right lumbar and pelvic pain; she had a complete double ureter and pelvis, both of which showed marked urinary infection. I had treated her by nonoperative measures for three years, with only temporary relief. At operation, I avoided nephrectomy because good renal function persisted.)

When asked if they were glad they had had this operation, twenty-four patients replied in the affirmative, four said they "did not know" and two replied in the negative.

#### OBJECTIVE RESULTS

Ten of these patients returned this year at my request for ureteropyelographic studies. As might be inferred, all were among those who considered themselves well, but I was interested in proving the present condition of their renal position and urinary drainage in an accurate manner.

Not one of these patients had an emptying time of more than seven minutes after the pelvic instillation of 8 cc. of 12.5 per cent sodium iodide solution. In eight, the outline of the pelvis and ureter were normal, and in two there was still a moderate pelvic dilatation without retention. In one, there was a broad angulation of the ureter without obstruction (figs. 4, 5 and 6).

#### SUMMARY

1. Freeing of the kidney and ureter and suspension of the kidney (nephrolysis, ureterolysis and nephropexy) is an efficient and justifiable operative procedure when applied to patients who are carefully studied.

2. The diagnosis rests only on accepted urologic procedures utilizing modern methods of ureteropyelography and consideration of upper urinary tract mechanics.

3. The mere presence of abnormal renal mobility is not to be considered pathologic unless clinical and objective study demonstrates definite indication of deficient ureteral or pelvic drainage.

4. A satisfactory operative technic is described which varies somewhat from previously reported methods.

# EPITHELIOMA OF THE PENIS

## TREATMENT WITH RADIUM AND THE ROENTGEN RAYS\*

ARCHIE L. DEAN, JR.

This paper is a clinical study of seventy-five cases of epithelioma of the penis in which examination and treatment were given in the department of urology of the Memorial Hospital in New York.

### ETIOLOGY

The ages of the patients at the time of onset of the disease ranged between 21 and 79, with the decades represented as follows: between 20 and 30 years, 8 per cent; between 30 and 40 years, 13 per cent; between 40 and 50 years, 23 per cent; between 50 and 60 years, 29 per cent; between 60 and 70 years, 17 per cent, and between 70 and 80 years, 9 per cent. Seventy per cent of the patients were married, 11 per cent were widowers and 19 per cent were single. They had engaged in every type of occupation. Nine per cent were negroes and 91 per cent were white. No Jews appeared in this series. Fifty-two per cent were born in the United States; 11 per cent were Italians, 9 per cent were Irish, 5 per cent were Germans, 4 per cent were Cubans, while natives of Austria, England, Scotland, Finland, Russia, Denmark and Sweden were included. Sixty per cent said that they had not had previous venereal infection, and 24 per cent admitted that they had had gonorrhea. The presence of syphilis was admitted or proved in 20 per cent, while 2 per cent had suffered with chancroid. In 4 per cent there had been a mixed infection of syphilis and chancroid, and in 2 per cent of syphilis and gonorrhea.

The outstanding factor in the causation of penile cancer is a tight prepuce, which is difficult or impossible to retract. Retained secretions are a well recognized source of chronic irritation. Hard, inspissated smegma is a potent factor of mechanical irritation, and the presence of fatty acids may furnish irritation of a chemical nature as well. For this reason the disease practically never is seen among Jews or Mohammedans. In this series, there is no record of a case of epithelioma of the penis developing in a man circumcised in infancy.

Syphilitic ulcers and scars are mentioned frequently as of etiologic importance. Leukoplakia is recognized as a precancerous lesion. In addition, papillomas of the penis have been known to undergo malignant degeneration, while accidental trauma of various degrees of violence, in certain instances, has been described as a contributing cause. In my

---

\* From the Department of Urology, the Memorial Hospital, New York.

experience these factors have seemed of but secondary importance when subjected to critical examination. Phimosis alone was found in 74 per cent of the patients. A positive diagnosis of syphilis was made in 20 per cent of the cases, but these men all had a certain degree of phimosis as well. In 3 per cent, leukoplakia unquestionably preceded the cancer, but each of the patients had submitted to a circumcision in adult life, probably for sufficient cause.

#### SYMPTOMATOLOGY

The first symptom noticed by 73 per cent of the patients was a small sore on the penis. The most common site for the primary lesion to appear was somewhere on the glans. Nine per cent of the men first were aware of irritation followed by a small sore; 5 per cent suffered from paraphimosis, circumcision revealing a carcinoma, while 5 per cent first saw warts beneath a tight prepuce. The patients with leukoplakia noticed "scaly skin," which in one case appeared as a "corn."

It is noteworthy that in practically all of the cases, even though phimosis and chronic balanitis had been present for years, a condition appeared recognized by all as something decidedly different, even though its nature was not appreciated. Moreover, in the great majority of cases, even though an irritated condition had been present for a long time, the area of true epithelioma was small when it was first noticed.

As the disease progressed, the lesion gradually increased in size. In 58 per cent of the cases, pain developed. The pain was manifest by aching (22 per cent), stinging (14 per cent), a sharp and burning sensation (11 per cent) and itching (11 per cent). Other symptoms were paraphimosis, 5 per cent; bleeding, 5 per cent; difficult urination, 5 per cent; frequency of urination, 3 per cent. Usually there was discharge of foul, purulent material from beneath an inflamed prepuce. Frequently, the same patient had a combination of these symptoms, but the usual history was that a sore appeared which steadily increased in size, and soon became painful.

#### PATHOLOGY

There are two clinical varieties of epithelioma of the penis, the papillary and the flat. The papillary tumor is cauliflower-like in appearance. It consists of a densely matted villous overgrowth. The contour of the tumor as a whole is characterized by the broadness of its base in relation to its height or thickness. Areas of slough are present on the surface. The individual villi differ from the slender, elongated and pointed structures of benign papilloma in that they are shorter, thicker and club-shaped.

The flat carcinoma is usually an indurated area with an ulcer of irregular outline in the center. The entire ulcerated area usually is covered with a foul grayish or greenish-yellow slough.

An early lesion consists of a superficial ulcer superimposed on a broader, indurated base. Later, so great is the destruction of tissue that the tumor seems to be composed of an extending, sloughing ulcer surrounded by a narrow zone of induration.

Histologically, both the papillary and the flat lesions are squamous carcinomas. Each type spreads by progressive involvement of contiguous structures, while at the same time it excavates more deeply. Buck's fascia, owing to its relatively dense consistence, is a natural barrier to the superficial tumor. When this structure has been penetrated, and the cavernous tissue has become involved, at the Memorial Hospital the prognosis is promptly said to be more grave and the type of treatment altered.

Metastases occur by embolism. Lymphatic permeation is believed to be a later stage, in which cancer-emboli, caught somewhere in the lymph-channel, grow in the directions of lesser resistance.

The superficial areas of the penis are drained by lymphatics which communicate with nodes in the groins. The deeper tissues are drained by vessels which accompany the dorsal vein of the penis to nodes in the pelvis. On this account, and because cancer of the penis remains superficial for some time, it is the inguinal nodes which are examined for earliest metastases.

In general, metastasis occurs rather later in the course of the disease. On the other hand, there is evidence suggesting that certain methods of treatment, especially those in the nature of incomplete destruction, are conducive to early metastasis.

Ulceration of the primary lesion occurs early, and the environment of filth results in secondary infection becoming a prompt and constant superadded factor.

A study of the condition of the inguinal nodes of the patients in this series is interesting. Inguinal adenopathy was present in 85 per cent; in 15 per cent there was none. Of the enlarged nodes, 44 per cent were diagnosed as metastatic carcinoma; 56 per cent were considered purely inflammatory. Of the 44 per cent diagnosed as cancerous, 85 per cent (37 per cent of all patients), were proved to be such either by histologic study or by subsequent developments. The remaining 15 per cent (7 per cent of all patients) were proved to be inflammatory. Of the 56 per cent of the enlarged inguinal nodes originally diagnosed as nonmalignant, in not a single instance has cancer developed.

#### DIAGNOSIS AND TREATMENT

The diagnosis of epithelioma of the penis should be made histologically. A biopsy carefully performed with a sharp razor does little if anything toward hastening metastasis. There is no doubt that in most

instances a competent physician can make a correct diagnosis clinically; still the records show much valuable time lost by inappropriate therapy before the true nature of the lesion is discovered. Moreover, following Broder's grouping of malignant tumors, scientific treatment is based on the intimate details of cellular structure and arrangement. This is revealed only by the microscope.

The prophylactic treatment of epithelioma of the penis consists in the circumcision of all male infants.

In the use of physical agents in the treatment of epithelioma of the penis, only intense irradiation is effective because squamous carcinoma is highly radioresistant. For this reason and also because of greater convenience, radium applicators are employed at the Memorial Hospital in dealing with the primary lesion.

In the management of metastases, the difficulties are still greater owing to the overlying tissues which must be penetrated by the rays before they are delivered within the tumor. Under these conditions, a combination of high voltage roentgen rays and the radium pack is most effective.

The details of the treatment of individual cases are modified according to the size of the primary tumor, how deeply it has penetrated, and on the presence or absence of metastases. Of course, the patient's general condition is of the greatest importance. In all cases an attempt is made to obtain an accurate estimate of the extent of the penile lesion. Occasionally, this requires a dorsal slit or lateral incisions of the prepuce. Whatever form of treatment is adopted, a strenuous effort should be made to obtain as clean a field as possible. This diminishes inflammation about the primary tumor and to a corresponding degree reduces absorption of the products of inflammation by the inguinal nodes.

The importance of infection co-existing with metastases in lymph nodes cannot be overestimated. Such a condition is not amenable to external irradiation, and when interstitial irradiation is employed and emanation tubes are buried in the nodules, a discharging sinus often follows. The result is a rapid spread of the disease.

Owing to the fact that the majority of the patients who present themselves show regional adenopathy, and because it is difficult to differentiate between inflammatory and cancerous nodes, the groins of all patients are treated as a routine with high voltage roentgen rays, employing exposures of 320 milliampere minutes, a focal distance of 50 cm., a spark gap of 90 mm., filtration of 0.5 mm. of copper and 1 mm. of aluminum and 200 kilovolts.

GROUP 1.—If the primary lesion is 2 cm. or less in diameter, superficial, and metastases cannot be detected, external irradiation alone is

used. The tumor is treated with a radium plaque,<sup>1</sup> the dose being 1,200 millicurie hours per square centimeter, at 1 cm. distance.

There were thirteen patients in this group. Twelve, or 92 per cent, are living, without signs of disease. One patient died at another hospital following an operation. One of these men lived from twelve to eighteen months; three from eighteen to twenty-four months; one, from two to three years; two, from three to four years; two, from four to five years; two, from seven to eight years and one, for nine years four months after the first irradiation.

Occasionally, the carcinoma, though small, has penetrated deeply into the cavernous tissues. Frequently, undermining has gone so far that the deeper parts of the tumor are relatively inaccessible to intense external irradiation. In such cases irradiation with the plaque is followed by a conservative amputation.<sup>2</sup> Four patients were so treated. All of them are living and well; one, from two to three years; two, from four to five years and one, from six to seven years after the first irradiation.

GROUP 2.—If the primary tumor is larger than 2 cm. in diameter and metastases are not found, the treatment of choice is usually irradiation with the plaque followed in from three to four weeks by a conservative amputation. On those patients who present extensive tumors which have already destroyed a considerable proportion of the penis, a similar amputation is performed without preoperative irradiation.

In this group there were thirty-one patients. Nineteen, or 61 per cent, are living and well; five, or 16 per cent, are known to be dead, while seven, or 22 per cent, are lost from the records and are classified as dead. The living have survived: one, from eighteen to twenty-four months; four, from two to three years; two, from three to four years; four, from four to five years; three, from five to six years; four, from seven to eight years and one, from eight to nine years after the first irradiation.

GROUP 3.—Eighteen patients were first seen with both a primary lesion and metastases. Three, or 16 per cent, are living, two with signs of disease; fifteen, or 82 per cent, are dead.

---

1. The plaque is a box 1 cm. square which contains radium emanation enclosed in silver capsules, the walls of which are 0.5 mm. thick. The side of the box which overlies the tumor is made of brass, 1 mm. in thickness.

2. Conservative operation is believed to be a distinct advance in rational therapy. Amputation is performed 2 cm. proximal to visible or palpable evidence of disease. The success of the measure depends on the knowledge that metastasis is by embolism. It is not at all uncommon to preserve so much of the organ that coitus is possible.

When there are definite inguinal metastases, the patient receives a high voltage roentgen ray exposure of 320 milliamperere minutes at a distance of 50 cm., filtered through 0.5 mm. of copper and 1 mm. of aluminum combined with a radium pack exposure of 9,000 millicurie hours at 6 cm. distance filtered through 0.5 mm. of silver and 1 mm. of brass. At the end of from three to four weeks a block dissection may be performed, or if a reasonable amount of regression is noted it may be decided to carry on with irradiation only. In those patients whose general powers of resistance have been seriously depleted by age, disease, or both, no inguinal dissections are performed. The palliative effect of irradiation is satisfactory in these cases, and it is accomplished without discomfort or shock.

GROUP 4.—Nine patients were referred for postoperative irradiation. Of these, two were considered free from disease at the first examination. They are alive and well six years, ten months and eight years, respectively, after the first treatment. The remaining seven men had metastases. However, two are still alive, three years and five months and nine years,<sup>3</sup> respectively, after the first irradiation.

#### COMMENT

1. When a large portion of the penis is involved, even if the tumor is superficial, irradiation alone is not recommended though probably it could control the disease. A conservative operation is thought preferable (1) because it removes but little more of the organ than has already been destroyed by disease; (2) a large irradiated surface is unduly painful; (3) even should the remains of the penis be salvaged, the result probably would be a misshapen organ of but slight utility.

2. When there has been an extensive primary tumor and metastases, it has been impossible to provide more than palliation. If the general condition of the patient seemed to permit, the customary procedure was followed and amputation of the penis was performed, together with a radical dissection of the groins, bilateral if indicated. This was preceded by irradiation. The results were unsatisfactory. The disease seldom was eradicated and infection of the wound was frequent.

A majority of the patients in this group did not appear able to survive such operative treatment and were given irradiation. The effects illustrate how inadequate the present methods of irradiation therapy are in combating disseminated squamous carcinoma in the presence of secondary infection.

In studying the end-results in these cases and in those of others, it seemed that some method should be adopted whereby operative shock

---

3. For greater value in estimating end-results, only those patients who have been under observation for a year or more are included in this study.

might be lessened and postoperative infection decreased. Therefore, at the Memorial Hospital the management of these advanced cases was recently undertaken as follows: With the patient under spinal anesthesia with a preliminary injection of ephedrine, the penis is amputated. Every precaution is exercised to obtain prompt healing by primary union. This operation is attended by hardly any shock. As a result of the removal of the source of infection there is an end to lymphatic absorption, and inflammation in the regional nodes subsides. Relieved of the infected and frequently painful tumor, the general health of the patient usually can be built up. Evidence of adenopathy decreases and irradiation is more likely to prove effective. Later, when block dissection of the groins is performed, no time is consumed in amputating the penis, and the frequency of postoperative suppuration may be diminished.

#### CONCLUSIONS

1. The results obtained with the use of radium applications alone have been highly satisfactory in those cases of epithelioma of the penis in which the tumor was 2 cm. or less in diameter and reasonably superficial.

2. With the more extensive tumors, surgical measures are necessary, and irradiation is a useful adjunct.

3. Radical extirpation of the penis in every case of epithelioma is unnecessary. A conservative amputation effectively removes the disease and frequently preserves function.

4. Secondary infection of the regional lymph nodes, which occurs regularly in the presence of a sloughing penile tumor, is a grave complication to either surgical or irradiation therapy.

5. Present methods of irradiation are inadequate to check the metastases of squamous carcinoma in the presence of secondary infection.

30 East 40th Street, New York.

# "DE L'AUSCULTATION MÉDIATE" OF LAENNEC\*

HENRY R. VIETS

A study of the various editions of Laennec's "De l'Auscultation Médiate," as published in France, England, Germany, America, Belgium and Italy, within a relatively short time after the initial appearance of the book in 1819, gives one a clear idea of the importance of Laennec's work in the eyes of his contemporaries. The demand for the volume must have been great, for, although the size of the editions is not known, nineteen distinct printings have been traced in the period of twenty years, from 1819 to 1839. Seven of these were in French, eight in English, three in German and one in Italian. Another English edition appeared in 1846, making twenty well known early issues. Since the latter date, a number of reprints and extracts of the book have appeared, such as the splendid translation of selected passages by Sir William Hale-White, London, 1923, and the French reprint in 1879, of the entire second edition of 1826.

All the editions, with the exception of the 1837 Bruxelles edition, are found in the excellent collection of Dr. Henry Barton Jacobs of Baltimore. No one public library in America seems to have the complete list, the nearest to it being the collection in the Library of the Surgeon General's Office at Washington. A rare association copy is owned by Dr. John Farquhar Fulton, the title page of which is reproduced. This book apparently was once Laennec's personal copy, later given by him to his uncle, who was so kind to him during his early life.

*Editions in French.*—All the four important French editions are well known and are found in most of the larger American libraries. They were first published in Paris in 1819, 1826, 1831 and 1837. In the second edition, the title was slightly changed and the contents were entirely rearranged. Laennec, in the first edition, described the stethoscope and showed how it might be applied in the auscultation of the chest, but did not lay special stress on its value as an instrument of differential diagnosis. In the second edition, however, he took up the various diseases in order and showed what might be found, in addition to the results of the clinical examination, by the use of his stethoscope. Thus, by altering his point of view, he greatly increased the value of his work. The third edition (1831) appeared in three volumes instead of two, various notes having been added by his nephew, Mériadec Laennec. The fourth edition was also in three volumes, and, in addition to Mériadec Laennec's notes, there were notes by Professor Andral. All issues came from the publishing house of J.-S. Chaudé, the first edition only being issued with J.-A. Brosson.

Three editions in French were published at Brussels, the first in 1828. In addition to Dr. Jacol's copy, there is one in the Library of the Surgeon General's Office at Washington. This edition was

---

\* Read in part, at the meeting of the Boston Medical History Club, May 10, 1926, and published in the Boston Medical and Surgical Journal 195:208, 1926.

reissued in 1834, with a new title page, the Avertissement (pp. i-iv) by Mériadec Laennec and a supplement of sixty pages containing his notes taken from the third French edition of 1831. In the Osler Library copy, examined by Dr. W. W. Francis, the librarian, two 1828 title pages are pasted (with printed side concealed) inside the 1834 paper covers.

The third edition, published in French at Brussels, 1837, is "an exact reprint of Andral's fourth French edition with all the 'Notes' of that edition including those of Mériadec Laennec and of Andral. In place of the original three volumes of Andral, this edition is reduced to one volume by increasing the size of the page to  $9\frac{1}{2}$  by  $6\frac{1}{4}$  inches and using smaller type. This allows the 1,956 pages of the French edition to be reduced to 514 in the Brussels edition. The book has been very carefully edited, as in the 'Table of Contents,' which appears at the end, the various headings are paginated exactly to fit the volume. The plates are beautifully reproduced, even more artistically than in the Andral edition, where they seem to be woodcuts, and here they look almost like mezzotints" (Jacobs). It was printed at the Imprimerie Gambart de Courval. A copy is owned by Dr. Lawrason Brown, Saranac Lake, N. Y.

*Editions in English.*—The first English edition appeared in 1821, two years after the first French edition. It was a one volume work, translated by John Forbes,<sup>1</sup> who rearranged the contents completely. Forbes probably used the second French edition, which had appeared the year before, in compiling his second English edition (1827). To this edition he added notes and a sketch of the author's life. The third English edition, two years later (1829), differs only slightly from the second English edition, there being no intervening French edition. Forbes used the third French edition of 1831 as a basis for another English edition, the fourth, in 1834. The last French edition (1837) was not translated, as a fifth edition, until 1846. Forbes was replaced by a new translator, whose name is not known.

The 1838 English "edition," noted in the article on Sir John Forbes in the "Dictionary of National Biography," cannot be found. Although Forbes may have prepared the notes, it does not seem likely that it was ever printed.

The first American edition, published in Philadelphia by James Webster in 1823, is a reprint of the first English edition (1821). There

---

1. Sir John Forbes (1787-1861) apparently saw the value of Laennec's work when many physicians treated it with contempt. He also translated, three years later (1824), Auenbrugger's important work on "Percussion," first published in 1761, which had long remained unknown to English physicians. Attention had been called to its importance in France by Corvisart (1808). Thus, it took over sixty years for Auenbrugger's "Inventum Novum" to reach the great majority of English physicians, while, on the other hand, Laennec's "De l'Auscultation Médiate" was translated into English two years after its first appearance in Paris.

apparently was no American edition to correspond with the second English edition in 1827. Was it possible that the demand in America for this extraordinary work was not so great as it was in England, or did the wise Philadelphian publisher issue a large enough first edition in 1823 to cover the demand of the sparsely populated country? At all events, a new publisher, Samuel Wood and Sons, New York, brought out the second American edition in 1830, which corresponds with the third English edition of 1829. The third American edition, in 1835, was a reprint of the fourth English (1834) edition. In 1838, the fourth American edition was issued, which was translated from the third and fourth French editions.

*Editions in German.*—A German edition was published at Wiemar in 1822, a translation of the first French edition. Another appeared ten years later, translated from the French by Meissner and published in Leipzig. The third edition, in 1839, is a cheaper reprint, by the same publisher, of the 1832 issue. All these editions are rare in America; all three are in the Jacob's Library; the first, only, is in the Library of the Surgeon General's Office.

*Edition in Italian.*—The Italian edition, published from 1833 to 1836, one volume each year, was a translation of the third (1831) French edition, with the notes by Mériadec Laennec.

# DERMOID CYSTS OF THE OVARY

## ROENTGEN OBSERVATIONS

RAMSAY SPILLMAN

That dermoid cysts of the ovary frequently contain bone and teeth has been known to many generations of physicians. That this property can sometimes be turned to account in the diagnosis of these cysts has received comparatively little emphasis in medical literature, and it is for this reason that the following case is presented, together with a review of the scanty bibliography:

### REPORT OF CASE

A woman, in the fourth decade of life, recently married, consulted Dr. E. W. Pinkham in January, 1925, on account of having become conscious of a mass in the abdomen. The menstrual and other aspects of the history were not in keeping with the condition being pregnancy, and the diagnosis of a cyst of the ovary was made. The patient came to me for a roentgen examination, to see whether any further light could be thrown on the condition. A roentgenogram of the abdomen and pelvis showed no evidence of a fetal skeleton. Certain shadows overlying the left side of the sacrum were noted on the film, but their nature was not recognized until after the operation. Dr. Pinkham did not see the film before the operation, so the failure to interpret these shadows is not his. He removed the cyst in February, and the patient made a prompt and uneventful recovery and has been in the best of health since. She has not borne any children.

As can be visualized from the two illustrations, the position of the shadow confirms the finding that the cyst extended almost to the level of the umbilicus; it was about 18 cm. in diameter. The cyst was removed intact, and when it was opened for examination, the characteristic fatty fluid gushed out, together with a mass of long brown hair. With the walls collapsed, the bony structure could be made out by palpation.

I requested that the cyst be given to me for roentgen examination, and the result is shown in figure 2. A well-developed tooth of the form of an upper cuspid can be seen, and lying obliquely over it is another tooth. The film clearly showed the root-canal of the cuspid tooth. The curving bone extending upward and to the reader's right is a fair attempt at the formation of a maxillozygomatic region. A distinct suture line was found between the two parts of the bone.

When the film of the extirpated cyst is compared with the film of the pelvis, the structure can be visualized. However, the slight blurring on the film of the pelvis prevented recognition of the denser part of the shadow as a tooth, and I believe that this blurring is due to the proximity of the cyst to the left hypogastric artery, which doubtless transmitted impulses to it during the five seconds of exposure. The distinctness of the other structures shown lends weight to this belief.

The roentgenogram of the collapsed cyst indicates that this method of examination should be of use as a means for the orientation of sections from such a tumor.

The failure to recognize the dermoid characteristics of this cyst before operation fortunately in no way complicated either the operation or the outcome. The literature shows, however, that teeth in dermoid cysts have been mistaken for ureteral calculi, as will be shown further on.

The first roentgen report in the literature of dermoid cysts of the ovary appears to be that of Wilms,<sup>1</sup> who in 1900 published an illustra-

Fig 1.—Shadows over left side of sacrum in dermoid cyst of ovary.

tion of a roentgenogram of a cyst removed from a girl, aged 12 years, by Birch-Hirschfeld. This plate shows a cyst of approximately the size of the one reported here, but instead of a formed bony structure, there are numerous small dense structures, some of which appear to be teeth. In his brief description, Wilms called attention to the tendency of these growths to form structures of the mouth, i.e., teeth and maxillary bones.

1. Wilms, M: Verwertung der Röntgenographie zum Studium der Geschwulste, Beitr. z. Geburtsh u. Gynäk, 3:367, 1900

In 1911, Pagenstecher<sup>2</sup> called attention in his textbook to the fact that "some tumors contain bone . . . in teratomas and fetal inclusions bone is found," and stated that in such cases the roentgen examination is of aid.

In 1913, Gosset<sup>3</sup> reported the case of a girl, aged 14 years, who for four years had had pains which were believed to be due to chronic appendicitis. Roentgen examination showed a small triangular shadow

Fig. 2.—Appearance of dermoid cyst of ovary after removal.

in the region of the lower end of the right ureter. Ureteral catheterization was not done. It was decided to remove the appendix, and a cyst "the size of an orange" was found in the right ovary, and was removed. It measured 6 by 5 cm. The shadow of the supposed stone apparently was due to a tooth in the cyst.

2. Pagenstecher: *Die klinische Diagnostik der Bauchgeschwulste*, 1911, p. 63.

3. Gosset: Kyste dermoïde de l'ovaire droit avec production dentaires décelées à la radiographie et pouvant faire penser à un calcul de l'uretère droit, *Bull. et mém. Soc. de chir. de Paris* 31:709 (May) 1913.

In 1915, Josephson<sup>4</sup> reported a case in which the diagnosis of ovarian dermoid cyst was established beyond question before operation, by the demonstration of a tooth, in which the root canal could be distinctly seen. The diagnosis of a dermoid cyst with a twisted pedicle was fully confirmed by operation. He said "It is unusual that a diagnosis in a case such as the above mentioned can be made without doubt, but in a case like this where the differential diagnosis is important in indicating the operation, the x-ray findings are very valuable. However, dermoid cysts are not generally visible on x-ray plates . . . In the case described, the sharp picture of the tumor may be explained by the coagulation of blood in the tumor." The roentgen diagnosis was made by Dr. Soderlund.

Robert Knox<sup>5</sup> in his textbook (1917) published a plate showing teeth and bones in a dermoid cyst in situ, and said, "an interesting case of doubtful shadow in the line of the ureter is recorded by Thurstan Holland, where the only indication against the shadow being that of a ureteral stone is its unusual direction in relation to the ureteral line. It was found at operation to be due to a tooth in a dermoid cyst."

In 1920, Sonntag<sup>6</sup> published an account of a case in which a tooth-germ in a dermoid cyst was taken for a stone in the lower part of the right ureter. The examination was made without ureteral catheterization. The right ovary was composed of a tumor the size of a child's fist, and included a dermoid the size of a walnut, containing brown-red hair and two hard structures the size of peas.

In 1922, Dunet<sup>7</sup> presented a case of interesting dermoid formation involving both ovaries, with irregular formation of teeth in each one, the structures in the two ovaries being symmetrical; there were seventeen or eighteen teeth in either side.

In the same year, Edeiken<sup>8</sup> reported a case in which a girl, aged 17, had symptoms that led to provisional diagnosis of a stone in the right ureter, and the roentgen examination was made for that reason. A cyst showing a recognizable tooth was found in the left ovary. The cyst and a chronically inflamed appendix were removed at operation. In this

case the wall of the cyst showed in the film; the cyst was about the size of an orange. This is the first case I have been able to find in American reports.

In 1923, Pless<sup>9</sup> reported the case of a woman, aged 25. A film of the sacral region showed "a dense homogenous round shadow surrounded by another shadow 'like a yolk in an egg'" projected over the caudal portion of the sacrum. Dr. Roth-Bratislava removed a dermoid cyst the size of a goose egg. It contained a piece of bone the size of a nut, with tooth formation, and surrounded by hair. In the discussion of this case, Altschul spoke of the confusion of these teeth with stones in the ureter.

In 1923, Alexander<sup>10</sup> reported a case in which the roentgenogram showed a shadow in line with the ureter, but on a second examination, the shadow was 1 cm. to the left of it. At both examinations a ureteral catheter was in the left ureter. The shadow was recognized as not due to stone in the ureter, and a round mass "the size of an apple" had been felt; hence, exploration was performed and the cyst was removed. Its content was purulent. A tooth was found in the cyst, which accounted for the shadow. Alexander quoted Albers-Schönberg as warning of the confusion between these two sources of shadows in the pelvis.

In 1924, Brun, Cassute and Jaubert de Beaujeu<sup>11</sup> reported a case in which many shadows were found in the pelvis plate, some of them resembling teeth and others irregular bony structure, but not until operation was it recognized that the dermoid process involved both ovaries.

The latest report I have found is that of Aimé,<sup>12</sup> who in 1925 described a case in which the diagnosis was established before operation. The patient was a woman of 37, who had albumin and pus in the urine. The shadow of the cyst was demonstrated, and a pseudocalculus was shown in it. The cyst involved the left ovary and was 8 by 9 cm. in size. After its removal, the urinary symptoms subsided.

#### SUMMARY

The occasional occurrence of bones and teeth in dermoid cysts of the ovary makes it possible to identify these structures before operation in many cases. The occurrence of these teeth in the line of the ureter,

sometimes in cases in which the symptoms are urinary, makes it necessary for roentgenologists to be on guard not to be misled by the shadow of such a tooth taken for the shadow of a calculus. Ureteral catheterization is in order in the examination of female patients who have symptoms and roentgen manifestations of stone in the lower part of the ureter. When shadows are found in the roentgenogram of a pelvis of a woman and their nature is not evident, ossification in a dermoid cyst must be kept in mind. If routine roentgen examination were the rule in cases of enlargement of the adnexa, no doubt many more dermoid cysts would be identified before operation.

Finally, the roentgen examination of these cysts after removal is of interest and is of value to the pathologist.

# TORSION OF THE UNDISEASED FALLOPIAN TUBE

WILLIAM EDWIN GABE

Priestley, quoted by Garrison, stated that much of the history of gynecology up to recent times has been a series of "crazes"—a following of prevailing fashion. Before the days of gynecologic operations, nearly a century and a half ago, uterine displacement held the interest of gynecologists under the leadership of Hewitt in England, Velpeau in France and Hodge in America. This period marked the invention of a bewildering armamentarium of pessaries of all sizes, shapes and types. Soon, however, the great pioneers in the field of operative gynecology began to report their achievements—Baynham of Virginia, King of South Carolina, the great McDowell of Virginia, Lizars of Edinburgh, Sir Spencer Wells of London, Nélaton of France, and James Marion Sims of our southland. The advent of ether anesthesia and the application of the principles of Lister gave great impetus to the practice of gynecologic operations. Intense interest in various gynecologic conditions followed one another rapidly—pelvic cellulitis, oophorectomy, excision of the uterus and of its adnexa, extra-uterine pregnancy and cesarean section—all had their period of popularity. Emmet headed the school of skilled plastic gynecologists. Among great names in American gynecologic teaching centers, those of Howard Kelly and Joseph Price were foremost. A large number of gynecologic operations were devised, there being, for example, a score for uterine suspension alone, differing one from the other frequently in only a minute detail of technic. Based on the experiences of many thousands of cases, certain fundamental and typical operative procedures and practices, proved by the test of time to be sensible and productive of good results, became generally accepted. Even from these paths of safety there have been digressions—an instance being the advocacy recently on the part of several prominent surgeons of immediate operation in cases of acute salpingitis—a point settled it was supposed, once and for all, a generation ago. The recent use of radium and roentgen therapy has made some drastic therapeutic changes in the specialty. The present note in gynecology is sounded in the interest of organ conservation,<sup>1</sup> and especially in the attempt to train men, who will approach the subject from the physiologic and biochemical aspect, to study their cases more carefully and who might be looked on as physiologists and endocrinologists who do gynecologic operations.

The foregoing brilliant array of names makes it unnecessary to state that gynecologic pathology and surgical technic have undergone

---

1. Graves, W. P.: Problems of Organ Conservation in Pelvic Surgery, *Am. J. Obst. & Gynec.* **12**:217, 1926.

thorough study and elaboration under some extremely capable scientists. Physiologists, endocrinologists and biochemists have worked the field widely. The last decade, or more, however, has seen gynecology somewhat deserted for interests in other directions. The central nervous system and the liver have claimed the attention of the physiologist, while the interests of the abdominal surgeon seem centered almost entirely in the upper abdominal quadrants. To those who still think along gynecologic lines, the publication in 1921 of an article by Smith and Butler,<sup>2</sup> calling attention to twists in undiseased fallopian tubes of virgin young girls without demonstrable pathologic process that would explain the twist, was of greatest interest.

This torsion of a "normal" fallopian tube with the subsequent creation of an acute abdominal condition seemed an excessively rare situation by the number of case reports culled from existing literature. With increasing publicity regarding the condition, however, each year has shown a few more cases reported. A sharp distinction is to be made between torsions of the "normal" virginal tube, and the tube of the married woman. Here there is the possibility of infection and mechanical derangements accompanying or following pregnancy. By the "normal" fallopian tube is meant one in which, on careful pathologic examination following removal after torsion, nothing is found but hemorrhagic infarcts that are due to the extravasation of blood from the strangulation caused by the twist. Any history of an infection or pelvic trouble in childhood or infancy—as a vulvovaginitis—would bar the case from being considered because of the possibility of some latent, dormant tubal condition.

Cysts or tumors of ovaries with twist are common as causes of acute abdominal conditions requiring surgical treatment. According to Martin, 5 per cent of all ovarian tumors or cysts become thus strangulated, and some authorities put the figures as high as 47 per cent, as in the case of Küstner. Of less frequency, but of equal importance, is the twisting of fallopian tubes that are enlarged, such as hydrosalpinx, pyosalpinx or ectopic gestation. Anspach<sup>3</sup> reported eighty-eight such cases collected from the literature. From 1900 to 1921, there are to be found only twenty-five cases of twists of ovarian tumors occurring before puberty and only fourteen in normal adnexa at any period of life. The paper by Smith and Butler stimulated interest in tubal torsion to the extent that each year has added to the cases reported. Most of

3. Anspach, B. M.: The Torsion of Tubal Enlargement with Especial Reference to Pyosalpinx, *Am. J. Obst.* 66:553, 1912.

these have been in married women of middle life and do not properly come into the category here considered, as too many possibilities exist in such cases for tubal pathologic conditions that might lead to torsion. There are still so few cases reported of torsion of the tube in young virgin girls that each carefully studied case deserves being recorded. The following is an example of this rare condition.

#### REPORT OF CASES

CASE 1.—Miss M. L. C., aged 13, referred from Filmore, Ind., entered the Methodist Hospital on Nov. 17, 1922, complaining of pain in the right lower quadrant of the abdomen accompanied by nausea and vomiting. The family history was irrelevant. The patient had had pertussis, rubella, rubeola, chickenpox and typhoid fever during childhood. Her menses were established at 11 years of age, were fairly regular, the duration of the flow being from five to seven days; there was no dysmenorrhea. Her present illness began two days previous to admission with dull pain across the entire lower part of the abdomen, accompanied by nausea and finally vomiting. The pain gradually radiated to the right lower quadrant of the abdomen and became more severe. The patient had an involuntary bowel movement in bed, and her general condition was such that she was sent to Indianapolis for surgical treatment. Physical examination revealed an obese girl, 15 years of age, lying with her knees drawn up and on her right side, suffering considerable pain. The head and neck, extremities and thorax revealed nothing pathologic. The abdomen was the site of a thick layer of fat, was somewhat rigid on the right and was exquisitely tender over the right lower quadrant of the abdomen, the point of greatest tenderness being over McBurney's area. The patient had an unruptured hymen preventing a vaginal examination, and because of the signs and symptoms being typical of acute appendicitis, a rectal examination was not done. The temperature was 100 F.; the pulse rate, 130, and respirations, 24. The blood pressure was 118 systolic and 84 diastolic. The urine was normal. The blood count showed 4,700,000 red blood cells, 18,000 white blood cells with 78 per cent polymorphonuclear cells. The abdomen was opened under a diagnosis of acute appendicitis. Free blood-stained fluid was encountered at once. The appendix, although bound down by old adhesions, was not inflamed and was obviously not the cause of the present illness. On exploring the pelvis, a mass, the size of a large orange, was found occupying the site of the right tube. On proper exposure, this proved to be a twist involving the right tube only, the twist starting about 4 cm. from the uterus and occurring through two and one-half turns. The ovary on this side was normal, as were the adnexa on the opposite side of the pelvis. The strangulated blackened right tube was removed, as was the appendix, and the abdomen was closed (figs. 1, 2 and 3). The patient made an uneventful convalescence, going home on the sixteenth day. At the present time, nearly six years after her operation, she says she is in good health and has normal, regular menstrual periods.

Küstner's law, to the effect that right-sided adnexa twist from right to left and those of the left from left to right, has proved true in the large majority of the reported cases, and was true in the present case. Sanes,<sup>4</sup> Anspach,<sup>3</sup> and Smith and Butler,<sup>2</sup> show that twists occur in

---

4. Sanes, K. I.: Observations of Torsion of Ovarian Cysts with Report of Cases, *Am. J. Obst.* 71:76, 1915.

the right adnexa three times to one compared with the left. This may be explained first because there is more room on the right, since the sigmoid encroaches on the left pelvic cavity, and secondly because the peristaltic action of the cecum and the small intestine on the right is much greater than that of the sigmoid on the left.

At the time of Wells' <sup>5</sup> paper, in 1924, the condition of torsion of a "normal" fallopian tube had never been correctly diagnosed before operation, but in several subsequent case reports the diagnosis was made, due, no doubt, to the condition being called to the attention of

Fig. 1 (case 1).—Section of tube proximal to twist, showing the normal structure. There is no organic disease present.

those interested in pelvic diagnosis who had read the case reports in 1921 and 1924. When a diagnosis has been made it has usually been acute appendicitis, and Ehrenfest <sup>6</sup> stated that the mistaken diagnosis of acute appendicitis in these conditions is really an important clinical fact. Other than for the sake of scientific accuracy, the mistake is of small import, because either condition demands immediate surgical interven-

5. Wells, J. J.: Volvulus of Fallopian Tube in Case of Tuberculous Pyosalpinx Simulating Gonorrheal Pyosalpinx, *J. A. M. A.* **83**:30 (July 5) 1924.

6. Ehrenfest, H., in discussion on Richard Smith, R. R., and Butler, William J.: *Am. J. Obst. & Gynec.* **2**:545, 1921.

tion. Those cases reported in the literature show generalized lower abdominal pain becoming localized in the right lower quadrant of the abdomen (except in case of twist occurring on the left side) accompanied by a rise in temperature, nausea and vomiting, leukocytosis, and with an increase in the percentage of the polymorphonuclear cells. There may be various urinary disturbances. Jefferson<sup>7</sup> found cutaneous hyperesthesia over the buttock on the affected side in the distribution of the first lumbar nerve. Vaginal examination is usually impossible, or unsatisfactory, due to the age of the patient, as in case 1.

Fig. 2 (case 1).—Section of tube distal to twist, showing the extravasation of blood into the tissues due to mechanical strangulation, but with no evidence of organic disease present

Rectal examination in several of the reported cases has revealed a mass on the affected side—indefinite or at times readily made out as to form and size. For the sake of a correct diagnosis, therefore, every young girl in whom a vaginal examination is unsatisfactory or impossible, presenting symptoms and signs of acute appendicitis, no matter how typical, should have a rectal examination. This may not only reveal much of corroborative value in the diagnosis of the appendicitis, but

7. Jefferson, J. C : Torsion of Fallopian Tube, *Brit. M. J.* 1:55 (Jan. 9) 1926.

offers almost the only means of identifying a volvulus of a tube in such a situation. An exception might be made in those cases in which the pain localized the right lower quadrant is preceded by epigastric pain and the sequential train of symptoms and signs is almost pathognomonic of acute appendicitis.<sup>5</sup>

It is comprehensible how an ovarian cyst as large as an orange on a slender, weak stalk or pedicle, might become twisted with resulting strangulation. Neither is it difficult to understand the same in regard to a rounded, large hydrosalpinx, pyosalpinx or ectopic gestation at the

Fig 3 (case 1)—Section of tube distal to twist, showing infiltration of red blood corpuscles under the peritoneum.

extremity of the tube. These all offer the same mechanical situation; namely, a heavy, large mass on a slender stalk, easily bent and twisted, with a shutting off of the venous return first and the arterial next with a resulting passive congestion of the points beyond the twist, which may later even become gangrenous. Ovarian cysts usually are not adherent to surrounding structures, whereas hydrosalpinx and pyosalpinx are, hence twists occur much less frequently in the latter conditions. An explanation cannot be made with such facility with regard to the

case of tubes in virgins who had no history of previous trouble of any kind and in whom the adnexa on the opposite side were found normal.

The attempted explanation of how these torsions of normal tubes take place presents the most interesting aspect of the subject. Of the many theories, the following are perhaps the most plausible:

The first and most generally accepted theory is that the tube in question has an unusually long mesosalpinx that would allow undue mobility. A long mesovarium would predispose to the same condition in regard to the ovaries, a number of case reports of which are to be found in the literature.

The second most acceptable explanation is that the tube twists due to a passive congestion, and that the twist is imparted by the spiral course of the vessels supplying the tube. Payr<sup>9</sup> did a great deal of work in regard to this feature, removing a spleen and injecting the vessels and producing as much as 125 degrees torsion of the spleen by this procedure. The veins are longer and more flexible than the arteries in the mesosalpinx, and when passive congestion occurs, these assume a spiral form or course and impart a twisting motion to the tube or tumor. At least one case is reported in which this passive congestion occurred as a result of an infarct in the mesosalpinx, and the tube histologically was normal except for areas of extravasated blood as a result of the strangulation. To favor further the idea of passive congestion being an important factor might be mentioned the fact that a majority of the twists in "normal" tubes occur around the menstrual time. There are three case reports in the literature of torsion occurring in tubes histologically normal, in which the patients were pregnant; both conditions of menstruation and pregnancy are accompanied by a physiologic passive congestion of the pelvic organs.

The third explanation, championed especially by Anspach<sup>3</sup> and Norris,<sup>10</sup> assumes the patient to have a tube infected by a vulvovaginitis in childhood, later developing a hydrosalpinx which remains latent without symptoms and unrecognized until the acute torsion occurs. Anspach also felt that an exanthematous disease in childhood or an attenuated tuberculous infection might so damage the tube that it would be predisposed to torsion under favorable conditions later. Such generalized conditions, however, would probably involve the other tube. Likewise, such infection would probably seal the tube and involve the fimbria, whereas in several of the reported cases, the ostia of the tubes were mentioned as open and the fimbria normal. In the case reported here,

---

9. Payr, Erwin: Weitere experimentelle und klinische Beiträge zur Frage der Stieldrehung intraperitonealer Organe und Geschwülste. *Deutsche Ztschr. f. Chir.* 85:392, 1906.

10. Norris, C. C., in discussion on Smith and Butler; *Am. J. Obst. & Gynec.* 2:545, 1921.

the tube was normal proximal to the twist, the ostium was open and the fimbria of the customary appearance.

A fourth possible cause of twist might be external violence. In Darner's case,<sup>11</sup> the condition developed after the patient received a kick in the abdomen five days prior to operation. A severe blow might cause enough congestion of pelvic viscera with resultant circulatory change to bring about a torsion of a tube, as explained by Payr. Every surgeon has too often been surprised by the consequences of a blow on the abdomen not to take such a history seriously and believe almost any resultant pathologic process possible. The presence of small hydatid cysts of Morgagni, representing the remains of Gärtner's duct, attached to the fimbriated end of the tube being a factor in bringing about torsion must not be lost sight of. If small, they are considered a normal condition by Polak, but their presence in a twisted tube should throw them out of the category considered in this paper.

When one considers twist of the "normal" fallopian tube in the married woman, certain possibilities arise that make one feel the problem is somewhat different than in the virgin young girl. And yet the most careful study of some of these cases reveals nothing that can explain the twist other than the four possibilities that apply to tubal torsion in the virgin girl. The following cases illustrate this:

CASE 2.—Mrs. B. Y., aged 47, entered the Methodist Hospital on Oct. 16, 1925, complaining of pain beginning in the right lumbar region and radiating to the right lower quadrant of the abdomen, accompanied by nausea. She had been married twenty-six years and had had twelve children, all normal deliveries. Her family history was irrelevant. Her past history revealed pertussis, rubella, rubeola and chickenpox when a child; otherwise she had never been ill. Her present illness began three days before admission, with a dull aching pain in the right lower part of the back above the hip, with radiation "around the hip bone" to the right lower quadrant of the abdomen. Two other similar attacks had passed away leaving some "soreness"; the first occurred three months and the second two months before the present one. All three had been accompanied by nausea and vomiting. Movement of the psoas muscle was painful. The patient had finished a normal menstrual period just before admission to the hospital. There were no urinary symptoms. Physical examination revealed nothing abnormal in the head, neck, extremities and thorax. The abdomen was obese, rigid over the right side and tender over the right lower quadrant. A positive Schwartz sign was present. Rosving's sign was negative. Vaginal examination revealed a doughy mass in the region of the right adnexa. The temperature was 99.6 F.; the pulse rate, 96 and respiration, 20. The blood pressure was 126 systolic and 88 diastolic. The urine was normal. The blood count revealed 3,400,000 red blood cells, 7,800 white blood cells, with 77 per cent polymorphonuclear cells. The abdomen was opened under a diagnosis of twist of the right fallopian tube. The uterus, left tube and ovary and right ovary were normal. The right tube was black and swollen and twisted from right to left three times upon itself. Nothing further of a pathologic nature was found. A right

11. Darner, H. L.: Torsion of Normal Fallopian Tube. *Am. J. Obst. & Gynec.* 11:368, 1926.

salpingectomy and appendectomy were done. The patient was sent home well on the thirteenth day. The pathologist's report in brief stated that the tube measured "7 cm. in diameter and is markedly hemorrhagic. There is great edema of the mucosa, with much free hemorrhage into the muscularis. There is no evidence of an inflammatory reaction."

CASE 3.—Mrs. E. W., aged 27, referred from Colfax, Ind., entered the Methodist Hospital on April 8, 1925, complaining of sharp pain in the right lower quadrant of the abdomen, in the right lower part of the back and vomiting. The family history was irrelevant. She had had pertussis, rubeola, rubella, chickenpox, scarlet fever and pneumonia, all with good recoveries and without known sequelae. She had had one child of normal delivery. Her menstruation began at the age of 13, was of the four day type, was irregular always and accompanied by considerable pain the first two days. Her present illness began two weeks before admission to the hospital with rather sharp pain felt in the lower right lumbar region, which soon radiated to the right lower quadrant of the abdomen. Nausea and vomiting occurred a few hours later, with relief to the patient. She was able to be out of bed in a few days, but a constant "soreness" and tenderness in the lower part of the abdomen brought her to the hospital for relief. There were no urinary symptoms. Physical examination revealed a normal head, neck, chest and extremities. The abdomen was tense over the lower abdominal quadrant on the right; tenderness to palpation and considerable resistance and pain were evoked on bimanual examination of the region of the right adnexa. The temperature was 99.8 F.; the pulse rate, 110, respiration, 26. The blood pressure was 126 systolic and 86 diastolic. The urine showed a faint trace of albumin and a specific gravity of 1.003. It was normal microscopically. The blood count revealed 3,432,000 red blood cells, 9,200 white blood cells, with 73 per cent polymorphonuclear cells. The abdomen was opened under a diagnosis of right chronic salpingitis. Some free fluid was present in the lower peritoneal cavity. The right tube and ovary were twisted from right to left four times at a point 3 cm. distal to uterus. There were small areas of gangrene throughout the strangulated tissue. The uterus, left tube and ovary were normal to the eye and examining hand. Right salpingo-oophorectomy was followed by an uneventful convalescence. Pathologic examination of the specimen revealed beginning gangrene, edema and hemorrhagic infarction without any signs of infection or other pathologic process.

In both cases 2 and 3, the causative factor of the torsion is enigmatic. Due to the interest in the condition every effort was made to find some pathologic process in the tubes that might subscribe to the belief that a latent tubal infection was present, but only the results of mechanical strangulation were found. Both women, being married, were exposed to the possibility of specific infection, and both, especially the patient in case 2, with her many pregnancies, were the possible victims of some unrecognized, mild puerperal bacterial invasion. Considering the normal pelvic organs in cases 2 and 3, however, there is no reason why the torsion could not have occurred in the same obscure fashion as in case 1 and have been due to the same undetermined causes.

When the normal mechanics of the pelvic organs is changed by the presence of a large tumor, or the fixation of one or more organs, or by the adherence of one organ to another, there may occur torsion of a

fallopian tube which in itself is not diseased. While abnormal mobility of the fallopian tube has been advanced as the most probable cause of torsion, there seems no doubt of the importance of a certain amount of mobility being necessary. When this normal amount of mobility is reduced by pathologic processes in organs other than the tubes, torsion of the tubes may occur. The following case is an excellent illustration of this fact:

CASE 4.—Mrs. M. B., aged 45, referred from Clayton, Ind., entered the Methodist Hospital Sept. 16, 1927, complaining of severe pain in the left lower quadrant of the abdomen, vomiting and inability to straighten the left leg due to pain in the abdomen. Her family history was irrelevant. The patient had had mumps, pertussis and rubella as a child. Typhoid fever at the age of 9 was followed by an uneventful convalescence. She had a normal pregnancy with normal delivery at the age of 20. She began to menstruate at the age of 13 and was regular and normal until eight years before admission to the hospital, when her periods became profuse in amount and the length of time of menstruation changed from four days to eight and at times to ten days. Her present illness began two days before admission with dull pain in the left lower quadrant of the abdomen, which became suddenly sharp in character. Nausea and vomiting soon occurred. It became impossible to extend her left leg due to the pain it occasioned in the left lower abdominal quadrant. Physical examination revealed a thin woman, considerably dehydrated and appearing quite ill, lying on her side with the knees drawn up. No physical conditions of note were to be observed other than in the abdomen. A smooth, hard, centrally situated mass could be felt above the symphysis pubis and extending some 10 cm. above it toward the umbilicus. Extreme tenderness and spasticity were present over the left lower quadrant of the abdomen, the patient hardly allowing an examination due to the pain occasioned. A vaginal examination revealed a large, smooth, rounded tumor of the uterus that was fixed. Palpation of the adnexa was unsatisfactory owing to spasticity and lack of cooperation on the part of the patient. The temperature was 100 F.; the pulse rate, 90, respiration, 28. The blood pressure was 140 systolic and 80 diastolic. The urine showed a faint trace of albumin. The blood count revealed 4,130,000 red cells, 14,800 white cells, with 80 per cent polymorphonuclear cells. On opening the abdomen, a moderately large, calcareous fibroid of the uterus was found. It was firmly fixed to surrounding structures and could not be moved. The bladder was drawn over to the right and adherent to the uterine tumor. The right tube and ovary and left ovary were normal in appearance and to palpation. The left tube was black, swollen and twisted from left to right two and one-half times. A left salpingectomy was done quickly and the abdomen closed; the patient was in only fair condition at the end of operation. Her convalescence was rather stormy for a few days, but she was able to go home on the twenty-seventh day following operation. The fibroid tumor was exposed to the x-rays subsequently, and at present, eleven months after operation, is considerably reduced in size. The patient has gained 14 pounds (6.4 Kg.) in weight. Pathologic examination of the specimen showed nothing but the results of mechanical strangulation of the tube.

Operation is the only safe treatment in torsion of the fallopian tube. While some patients are acutely sick from the condition, it is astonishing how few symptoms and signs may be present from a gangrenous mass in the pelvis. Without operation, the danger of necrosis and

gangrene with infection and subsequent peritonitis cannot be lost sight of. Rupture with hemorrhage may occur. There may be cystic degeneration with fibrosis, and the case lapse into chronic gynecologic semi-invalidism. It is also conceivable that the acute torsion may subside completely without any untoward results in the future. All things considered, the condition may be classified with acute appendicitis, intussusception and intestinal obstruction in which operation should be done as soon as the diagnosis is made.

Torsion of the undiseased fallopian tube in the young virgin is rare; in the married woman uncommon, but not excessively rare. It may be caused by a number of mechanical conditions not fully understood. It must be added to the already long list of conditions to be thought of in diagnosing acute conditions of the abdomen. When pondering the question of whether or not to operate, it is well to remember that the symptoms and signs often belie the severity of the existing pathologic process.

# LESIONS OF THE POSTERIOR URETHRA IN CHRONIC GONORRHEA

CYSTO-URETHROSCOPIC OBSERVATIONS \*

ERIC STONE

This report is a study of 120 consecutive cases of chronic gonorrheal urethritis, seminal vesiculitis and prostatitis, in which cysto-urethroscopic examinations were made. The material was gathered both from private practice and from patients seen at the outpatient department of the Providence City Hospital. At the hospital, the press of an active public clinic prevented the use of this procedure in many cases in which it would have been applicable. However, the frequency of its employment among the private patients shows the extent of its usefulness. Of 200 consecutive cases in private practice cysto-urethroscopy was performed 143 times in 98, or 49 per cent, of the cases.

The McCarthy cysto-urethroscope was used throughout and for the initial examination was equipped with a Bugbee electrode of the delivery of a high frequency current to any suitable lesions. In a few cases further applications of this modality were made, or the instrument was used for catheterization or attempted catheterization of the ejaculatory ducts. In most cases no general or local anesthetic was used; in a few, in which sounds had demonstrated a hypersensitive posterior urethra, from 10 to 20 cc. of 4 per cent procaine hydrochloride was instilled. In no case was the discomfort of the procedure such that the patient objected to its further use.

All the cases showed signs or symptoms of the disease. The signs varied from clear urine with a few shreds or a morning drop to turbid urine or a diurnal mucoid drop. All cases showed leukocytes in the fluid expressed by massage from the urethral adnexa, varying in amount from 10 cells per high power field to 100 per cent pus. In only one case were gonococci present in urethral secretions at the time of the examination. Through some error the wrong smear was examined and the patient paid for the mistake by an attack of acute epididymitis coming forty-eight hours later. This was the only accident in the series. Many of the patients showed no symptoms, while most presented alone or in combinations such varying manifestations as frequency, dysuria, sacral backache, perineal pain, impotence, nocturnal or defecatory emissions, hypersexuality, dribbling or weakening of the urinary stream, etc.

\* From the Department of Venereal Diseases, Providence City Hospital.

Figure 1

Figure 2

Fig. 1.—Normal urethra: *A*, waterfall; *B*, posterior frenum; *C*, veru montanum with utricule visible in the midline; *D*, anterior frenum; *E*, pocket; *F*, external sphincter. Note that the ejaculatory ducts and the prostatic ducts are not visible, and that the mucous membranes are pale throughout.

Fig. 2 (case 539).—This case was characterized by defecatory emissions and perineal pain. The first and second specimens of urine were clear, with shreds. There was 100 per cent pus in the prostatic secretion. The condition was of seven months' duration. *A* shows enlarged and reddened veru montanum; *B*, hooded utricule with granulations; *C*, edematous cyst at proximal border of a deep "pocket" on the floor of which are granulating areas; *D*, transverse anular fibers of the compressor urethrae seen proximal to the pocket; *F*, external sphincter.

This paper is illustrated by photographs of scale models of various typical lesions, made by me, of monolith clay and painted the natural colors as seen through the cystoscope.<sup>1</sup>

#### LESIONS FOUND

In eight cases no pathologic condition was found in either the anterior or the posterior urethra. In only two cases was the disease limited to the anterior urethra, both showing inflamed glands of Littre and areas of granulation. In thirty-two other cases a pathologic condition was found both in the anterior and the posterior urethra. In seventy-eight cases the lesions were limited to the posterior urethra. Thus morbid processes were found in the posterior urethra in 91.4 per cent of the cases, but limited to this region in only 57.7 per cent, and appeared in the anterior urethra in 18.8 per cent, being limited to this region in only 1.6 per cent of the cases.

For the purposes of this study the region from the external sphincter to the meatus was considered as a whole since the two types of lesions found (inflamed glans of Littre and areas of granulation) were distributed indiscriminately throughout this part. The posterior urethra was considered in nine sections: (1) the internal sphincter; (2) the waterfall—the region from the internal sphincter to the posterior frenum—which lies on the floor of the urethra and covers the urethral fibers of the trigonal musculature; (3) the region on either side of the veru montanum, especially that part on which the prostatic ducts open; (4) the posterior frenum; (5) the veru montanum or colliculus; (6) the utricle, which is given a separate category as it was so frequently found the site of characteristic lesions; (7) the anterior frenum; (8) the "pocket," and (9) the external sphincter.

The use of the term "pocket" has not appeared in the literature and the region has not formerly been regarded as a distinct entity. It is used here to describe the area just proximal to the external sphincter which appears as a distinct concavity on the floor of the posterior urethra. It may be shallow or deep, some being sunk 2 cm. below the level of the rest of the urethra. It was recognizable in all but one case in this series. It is considered of some importance because in thirty-three cases it was the site of pathologic processes.

Table 1 shows the position, type and frequency of the lesions found in the posterior urethra. The figures refer to the number of cases in which the morbid processes occurred, not the number of individual lesions.

---

1. These models were demonstrated at the Scientific Exhibit of the Convention of the American Medical Association at Minneapolis, June 11-15, 1928.

Figure 3

Fig. 3 (case 581).—This case was characterized by a sensation of dribbling, but never any visible drop or stains. There was a "weak feeling" in the sacral region. The urine was clear, with shreds in the first specimen. There were 31 cells per high power field in the prostatic secretion. *A* shows streaked edema of the waterfall; *B*, dilated prostatic ducts; *C*, conical and reddened veru montanum; *G*, swollen and reddened anterior frenum; *D*, normal pocket; *E*, external sphincter.

Figure 4

Fig. 4 (case 553).—This case was characterized by urgency and dribbling. The infection dated back three years. There were few leukocytes in the prostatic secretion. *A* shows granulations on the waterfall; *B*, dilated prostatic ducts; *C*, rent into the prostatic body made one year ago by a sound; *D*, reddened but not swollen veru montanum; *E*, pocket.

An attempt to find any one typical picture was futile, as the 112 cases in which posterior pathologic process was found showed 100 different combinations of lesions. This may be clearly seen on examination of the accompanying illustrations. In one case there may be edema of the waterfall, edema and inflammation of the veru, edema but no inflammation of the anterior frenum, and granulations in the pocket, while in another there are polyps on the waterfall, granulation of the utricle, dilated prostatic ducts and an inflammataory reaction in the pocket. Furthermore, the greatest number and most pronounced lesions may not appear in those cases in which there is the greatest amount of adnexal infection or the severest symptoms. In short, there is a heterogeneous mixture of morbid processes.

\* Posterior frenum so often hidden by veru that the reading is low.

As confusing as this may seem, a grouping of the cases according to the nature of the lesions rather than their specific form considerably clarifies the problem. Under this classification a more uniform picture was found, the combinations falling into six general groups. The lesions were defined as to their basic pathologic process, i. e., inflammatory or edematous. Those lesions which were markedly hyperemic or areas of granulation were considered to be inflammatory in nature. Those consisting of a pallid edema were classified as purely edematous (table 2).

#### MECHANISM OF INFECTION OF THE POSTERIOR URETHRA

The multiplicity and confusing juxtaposition of different types of pathologic processes in the posterior urethra dependent on invasion by the gonococcus is explained by the routes taken and the stages of such infection.

Figure 5

Figure 6

Fig. 5 (case 321).—This case was characterized by pain on intercourse and mucoïd drop. The urine was clear, while there were shreds in the first specimen. There was 75 per cent pus on massage test. There had been three attacks, the first nine years ago, the last two years ago. *A* shows inflamed waterfall; *B*, polypi on the posterior frenum; *C*, inflammatory excrescence on the posterior frenum; *D*, dilated prostatic duct; *E*, inflamed veru montanum; *F*, granulations in the pocket.

Fig. 6 (case 544).—This case was characterized by morning drop and occasional sacral backache. The urine was clear; there were shreds in the first specimen. The prostatic secretion showed 40 cells per high power field. The infection dated back eight years. *A* shows edema of the waterfall; *B*, swollen but not reddened veru montanum; *C*, dilatation of the utricle; *D*, dilated right ejaculatory duct; *E*, reddened fluffy edematous swellings at junction of the veru and its anterior frenum; *F*, granular edema of the pocket; *G*, reddened and swollen area on roof of the urethra where it comes in contact with the veru.

The external sphincter is no great barrier to infection ascending by continuity and undoubtedly such a mode of extension is frequent. It is probable that the majority of cases in which the prostatic urethral infection is heralded by dysuria, frequency and tenesmus have suffered this type of invasion. There are, however, a great many cases which develop a chronic posterior urethritis (in inevitable conjunction with adnexal infection) that never pass through a recognizable stage of acute or subacute posterior urethral infection. Examination of the adnexa and the discovery of pus in the secretions is made because of an undue persistence of morning drops or shreds or the gradual onset of sexual symptoms. In these cases the glasses containing posterior urethral or vesical urine have at no time been turbid. The route of the infecting organism is probably along the lymphatics. A corroborative observation is that of 200 consecutive patients showing this insidious onset of adnexal infection, 95 per cent at one time or another had more or less marked inguinal adenitis; whereas 186 presenting sudden acute symptoms indicative of posterior inflammation had had inadenitis in 16 per cent.

TABLE 2.—*Type of Lesions*

Nature of Lesions	Cases	Nature of Lesions	Cases
	31	Evenly mixed..	11
	42	Scas	2
	10	No	2
	11	No anterior or posterior pathologic process.....	8

While a great deal remains to be learned about the lymphatic drainage of the urethra, certain facts are recognized at present. There are not only dorsal lymphatics draining into the inguinal glands, but lateral and ventral channels running up the length of the urethra which anastomose within the prostatic capsule with those from the posterior urethra and the especially well developed channels draining the veru montanum. These then form a network over the surface of the prostate, there receiving the channels from the prostatic follicles. The main channels lie between the glandular body of the prostate and its dense enveloping capsule. These offer plausible routes for posterior and adnexal invasion without postulating a necessary ascent along the urethral mucous membranes.<sup>2</sup>

2. Doble, F. C.: *The Urethra and the Urethroscope*. New York, Oxford University Press, 1923. Hain, R. A.: *An Anatomic and Clinical Study of the Posterior Urethra*, Northwest Med. 23:58 (Feb.) 1924. Urol. 7:165 (March) 1922. Watson, E. H.: *Development of the Veru Montanum*, Section on Urology, J. A. M. A., 1918, p. 143.

When once there has been established an infection of the prostate or seminal vesicles, there is soon a gradual infection of the mucous membranes of the posterior urethra because of the discharge of infectious material from the prostatic or ejaculatory ducts or by direct extension from the prostatic follicles. Even if the invasion has occurred by direct extension up the urethra, eventually the descending

Fig. 7 (case 521).—This case was characterized by itching in the urethra. The urine was clear, while there were floating shreds in the first specimen. The prostatic fluid showed 13 cells per high power field. The anterior urethra was normal. The condition was of ten months' duration. *A* shows mild streaked edema of the waterfall; *B*, dilated prostatic ducts; *C*, red and swollen veru montanum; *E*, red edema of the anterior frenum; *D*, white fluffy edema of the anterior frenum.

infection supervenes and keeps up the process. This double source of infection of the mucous membrane, with healing accomplished or in progress in some parts and inflammation still active in others, accounts for part of the confusion in the picture of chronic gonorrhea, especially

those features which are purely inflammatory, but not for all of it. A further factor is present. This is found in the areas of lymphangitis or perilymphangitis where the lymphatics lie adjacent to infected prostatic follicles. Where such areas occur, lymphatic drainage of the region they drain is blocked and edema of the urethral mucous membrane or intra-urethral structures occurs. This is irrespective of surface infection. If this obstruction occurs in one place there will be edema

Fig. 8 (case 153).—This case is characterized by mucoid morning drop. The urine was clear, with sinking and floating shreds in the first specimen. The prostatic fluid showed 50 cells per high power field. In I, 8/18/1922: *A*, shows brawny edema of the waterfall; *B*, dilated prostatic duct; *C*, saddle back edema and inflammation of the veru with dilated vessel; *D*, brawny edema of the pocket. In II, 10/13/1922: *A* shows polyp on the waterfall; *B*, dilated prostatic duct; *C*, normal veru; *D*, normal pocket. At the time of this examination, there was no morning drop. The urine was clear with rare mucous shreds in the first specimen. The prostatic fluid showed 18 cells per high power field.

Figure 9

Figure 10

Fig. 9 (P. C. H., 15178).—This case was characterized by shreds in the urine. Both specimens of urine were clear with sinking and floating shreds in the first. The prostatic secretions showed 10 per cent pus. The condition was of five months' duration. *A* shows area of cystic edema on the waterfall. Some of the cysts are so large and discrete that they resemble polyps and may be an early form of polypi. *B* shows pallid edema of the posterior frenum; *C*, dilated utricle; *D*, granulating area on the anterior frenum; *E*, the pocket showing transverse muscle fibers situated both proximally and distally.

Fig. 10 (case 499).—This case was characterized by mucoid morning drop. The urine was clear, with mucous shreds in the first specimen. The prostatic fluid showed from 2 to 3 cells per high power field. The infection dated back eleven months. *A* shows slight edema of the waterfall; *B*, large reddened veru montanum and anterior frenum, posterior frenum red but not swollen; *C*, brawny edema of the pocket. It appears like a group of low cysts but the overlying mucous membrane is reddened.

of the veru montanum or the frenums (figs. 2, 3, 6, 7, 8A, 9, 10, 12 and 13) or if at another point the edema will appear on the waterfall as streaked edema (figs. 3, 4, 5, 7, 8 and 10) or as bullous edema (figs. 9 and 11). Or if there is interference with the lymphatics draining the pocket there will be found in the structure cysts (fig. 2), brawny edema (fig. 6), bullous edema (fig. 10) or polyps (fig. 12). As one or more than one of these areas may be involved there may be a diversity of lesions.

Fig. 11 (P. C. H., 11827).—In this case both specimens of urine were turbid, with shreds in the first specimen. There was a morning drop. The prostatic fluid showed 1 per cent pus. The anterior urethra was normal. There had been one previous attack three years ago. The present infection was acquired six months before examination. *A* shows edema of the waterfall with cystic excrescences resembling polyps; *B*, two polyps on the veru montanum; *C*, dilated prostatic duct; *D*, inflamed veru montanum and freni; *E*, inflammation and edema of the pocket.

#### EVOLUTION OF POLYPI

Figures 9 through 13 show a progressive series of morphologic changes which suggest the possible steps in the evolution of polypi. In figure 9, on the waterfall, is an extensive area of bullous edema

Figure 12

Figure 13

Fig. 12 (case 762).—This case was characterized by pain in the perineum. The urine was clear, with mucous shreds in the first specimen. Massage test showed 10 cells per high power field. There were dilated vessels near the meatus in the anterior urethra. Onset of present gonorrhea occurred nine months ago; there had been one attack three years before. *A* shows edema of the waterfall; *B*, enlarged veru with dilated vessels; *C*, hooded utricle; *D*, polyps in the pocket.

Fig. 13 (case 632).—This case was characterized by shreds in the urine. The urine was clear, with shreds in the first specimen. The prostatic secretion showed 20 per cent pus. The infection was acquired twenty-one months ago. *A* shows a polyp on the veru montanum; *B*, pocket normal; *C*, external sphincter normal.

Microscopically, such areas show a slight proliferation of transitional cells, which are similar to those normally lining the posterior urethra, except that they are hydropic. There is below a markedly hydropic loose reticular tissue, which accounts for the boss formation. In figure 10, there is an area of cyst formation at the proximal limit of the pocket. This is the same process as the foregoing one, except that the bullae are fewer in number and are larger. In this particular case there is some inflammatory reaction on the surface but the basic pathologic process is the edema. There is hydrops of the proliferating epithelium and the reticular tissue with some leukocytic and lymphocytic invasion of the reticulum. In figure 11, there are two areas of interest. At the distal end of the waterfall (*A*) there is an area in which the edematous masses are more discrete and prominent than in the foregoing cases. This type of tumefaction shows under the microscope a further stage of epithelial cell proliferation in which at various points there is an invagination of the surface cells. Although these invaginations are morphologically glands the cells still retain their transitional character. There is a beginning fibrosis at the center of the substratum of reticular tissue and the lymphocytes predominate over the leukocytes as infiltrating cells. On the right hand aspect of the veru montanum there are to be seen two structures which closely resemble polypi except that no central vessel is visible (*B*). Here the gland structure is more marked and the process of central fibrosis has reached the point where there is blanching of the tissue so that the polypi appear white against the red of the surrounding inflamed surface of the veru. Figure 12 shows several identical structures in the pocket (*D*). Figure 13 presents a fully developed polyp springing from the left posterolateral surface of the veru montanum (*A*). Microscopically, this type of growth is made up of a covering membrane of transitional epithelial cells, still proliferating and desquamating at various areas. There are also many small glands in which the cells have become cuboidal and which have some active secretory process, as the lumen of the glands contain beside desquamated cells amyloid material. The reticular tissue is denser and, while there is still some leukocytic infiltration, the lymphocytes are greatly in excess and in places are so densely clustered that they suggest early lymph glands. There is also a dense fibrous core usually bearing a well developed vessel, which is visible as the structure is relatively translucent.<sup>3</sup>

Urol.* 5:177 (March) 1921. Randall, A.: Urethral Polyps, *Ann. Surg.* 40:325 (Sept.) 1914; A Study of Benign Polypi of the Male Urethra, *Surg. Gynec. Obst.*, Nov., 1913, p. 548.

## CONCLUSIONS

1. In chronic gonorrhea, the major urethral changes are found in the posterior urethra.

2. The anterior urethra shows a continuing pathologic process in only a minority of the cases.

3. The lymphatics draining from the penile and membranous urethra into the subcapsular lymph spaces of the prostate are a possible source of prostatic and seminal vesicular infection, and thus indirectly of posterior urethral infection.

4. The form which the posterior urethral lesions take is dependent on (1) localized areas of inflammation in various stages of healing, and (2) on sites of obstruction to lymphatic drainage of the area.

5. Polypi develop as a process of organization in persistent areas of localized edema.

# DYSPHASIAS OF CORTICAL RIGIDITY AND THEIR TREATMENT

A PRELIMINARY REPORT \*

STEELE F. STEWART

Dysphasia or difficult speech is to be distinguished from aphasia or absent speech. As a rule, dysphasia means difficulties that are central in origin as distinguished from those caused by peripheral lesions, such as difficulty in moving the jaw (dysarthria) or laryngeal disease (dysphonia).

Under the term dysphasia would be classified both stammering and stuttering. I have never encountered either of these difficulties in Little's disease and therefore I will not discuss them. In patients with cortical injuries, I have observed two types of disability: (1) difficulty in making certain sounds, for instance, *szv* in "sweet," or in giving the rough sound to a vowel, such as *h* in "hello"; (2) difficulty in slipping rapidly and easily from syllable to syllable. The latter disability may be obvious when the second sound is a repetition of the first, as in "mama"; but it is much more likely to be enhanced when the sounds are entirely different, as in "rab-bit." It may be most marked when the number of syllables is increased still further, or when the attempt is made to increase the speed of speaking. In the past the attempt has been made to overcome the difficulties with polysyllables by the development of "cog-wheel" speech.

I feel that the occurrence of aphasia and dysphasia has not received accurate statistical study. The confusing factors have been: (1) the diagnosis of aphasia in children who have not yet learned to talk, as in one child who did not learn to speak until 5 years of age, and (2) a confusion in terminology. Wallenburg<sup>1</sup> quoted Berkhardt to the effect that the aphasia is usually ataxic in type; obviously, he is referring to persons with dysphasia rather than to those with aphasia. This confusion is even more obvious when one observes the gathered data in table 1.

My experience corresponds more closely with that of Abercrombie<sup>2</sup> who stated that about one case in fifty is aphasic. Among eighty-three patients showing cortical rigidity only three (3.6 per cent) had true cases of aphasia, although it must be admitted that some young children

---

\* From the Orthopedic Clinic of the Children's Hospital.

1. Wallenburg, A.: *Ein Beitrag zur Lehre von den cerebralen Kinderlähmungen*, Jahrb. f. Kinderh., 1886, p. 384; referred to by Osler, W.: *Cerebral Palsies in Children*, M. News 53:29, 1888.

2. Abercrombie, J.: *Clinical Lecture on Hemiplegia in Children*, Brit. M. J. 1:1323, 1888.

in the series might have been aphasic. On the other hand, dysphasia was encountered twenty-three times in the same series, a figure which was comparable to those of either Wallenburg or Gaudard.'

It is interesting to observe that the difficulties of speech occurred in largest proportion among those who obviously had a rigidity involving all four extremities.

The marked preponderance of difficulty of speech among patients with right-sided involvements shows the close relationship to the predominance of right-handedness and would seem to indicate that speech is largely a unilateral development.

Peripherally, the utterance of sound consists in the exhalation of air under varying pressure through a series of modifying apertures which set up a certain series of vibrations. It may be further modified by the lengthening and shortening of the distance between the various points of interference by raising the larynx or by a change in the position of the tongue in respect to the palate and teeth. Furthermore, there may be a change in the size, shape and character of the resonance chambers, for

TABLE 1—*Incidence of Aphasia Among Spastic Patients*

Osler	150	13	8.9
Wallenburg	160	62	38.7
Gaudard ..	80	25	31.2

example, by the opening or closing of the posterior nares. Again, stops may be introduced by the tongue, teeth and lips so as to give explosive effects; in this respect people differ but slightly from the brutes with their various types of barks, whistles, etc. For the utterance of normal speech it is necessary to slip rapidly and easily from one sound adjustment to another in an unconscious manner at a rate of ten or more distinct sounds per second. In the adult this is largely a matter of habit and is as essential to speech as the escapement mechanism of the typewriter to orderly typing.

The following cranial nerves are concerned in the production of speech: (1) the fifth cranial nerve, which regulates and modifies the position of the jaw, both in a vertical and lateral position; (2) the seventh cranial nerve, which controls the perioral musculature and, with the (3) ninth cranial nerve, tends to lift and retract the pharynx; (4) the tenth cranial nerve, which supplies the intrinsic musculature of the larynx, pharynx and soft palate, and the (5) twelfth cranial nerve, which innervates the thyrohyoid mechanism and intrinsic musculature of the tongue.

3. Gaudard: Contribution a l'étude de l'hémiplégie cérébrale infantile, Thèse de Geneva, 1884; referred to by Osler (footnote 1).

The condition which exists in dysphasic patients is not paralysis, in the sense of an inability to move; it is rather a rigidity that affects certain muscles or sets of muscles. It is variable in degree, as shown by the following case.

## REPORT OF CASE

J. W., a girl, aged 9 years, had a duobrachial, duoskelic cortical rigidity of natal origin. The extra-ocular motions were all apparently normal. The facial muscles were well and equally controlled. The jaw could be opened and closed in a normal manner, but when lateral movement was attempted, it was seen that while the space between the two lower central incisors could be brought to the left to the interspace between the central and lateral incisors, motion to the right was restricted to a distance of only one-third the width of the central incisor. When the tongue was protruded slightly to the right, it could be projected well and could be placed on the roof of the mouth; attempts to move it from side to side, however, showed that it moved more easily and freely to the right than to the left. Deviation of the soft palate or stiffness of the throat was not found and the child could speak in a normal manner.

It has been shown to the satisfaction of most authorities that skeletal muscle has a dual innervation—one through the motor nerves and the other through the sympathetic nerves. Much experience has confirmed the observation of Royle<sup>4</sup> and Hunter that in persons affected with certain types of rigidity, the section of the sympathetic nerves leading to the affected part produces a relaxation of the rigidity and places the musculature under greater central control. I need not here be concerned with the method of action of the sympathetic nervous system on the musculature except to assert my belief in the explanation of Orbeli<sup>5</sup> that "it increases the force and amplitude of contraction and enhances the rapidity of development of tension" rather than in the explanation of tonic effect proposed by Royle.<sup>4</sup> The success obtained in the treatment of persons with rigidity in the extremities leads to the belief that the section of the sympathetic connections which exist between

4. Royle, N. D.: The Treatment of Spastic Paralysis by Sympathetic Rami-section, *Surg. Gynec. Obst.* 39:701, 1924.

5. Orbeli, L. A.: Neue zur Frage über die sympathische Innervation quer-gestreiften Muskeln, *Pavlov Jubilee Volume*, 1924, p. 403. Referred to by Fulton, John F.: *Muscular Contraction and the Reflex Control Movement*, Baltimore, Williams and Wilkin, 1926.

the sympathetic nervous system and the cranial nerves might lead to improvement in speech.

The connections of the sympathetic with the cranial nerves originate entirely from the superior cervical ganglion, passing at times through certain subsidiary ganglions. The fifth cranial nerve receives a triple supply of sympathetic nerves: from the submaxillary ganglion; from the geniculate ganglion, through the small superficial petrosal nerve, and from the otic ganglion, through the carotid plexus. The seventh cranial nerve receives its supply from the sympathetic nerve by way of the jugular ganglion of the vagus nerve. The ninth cranial nerve secures its supply from the petrous ganglion. The tenth cranial nerve receives large branches directly from the superior cervical ganglion. The twelfth nerve has a dual innervation: one directly from the superior cervical ganglion and the other through the ganglion nodosum of the vagus nerve.

The center of any operative measure designed to improve difficulty of speech lies, therefore, in the superior cervical ganglion. The ganglion also has certain other connections the nature of which should be taken into account: (1) the superior cardiac nerve, (2) the rami to the upper four cervical nerves and (3) the terminal branches to the carotid and cavernous plexuses which are concerned chiefly with the sympathetic innervation of the eye and ear. (The severance of these connections with the eye will be discussed elsewhere.) In connection only with the eye and the ear, no harmful effects have resulted from an operation on the superior cervical ganglion, so far as I have been able to observe; a partial ptosis may occur, but this gradually clears up. Moreover, the division of the superior cardiac nerve does not seem to have a harmful effect, and has been performed frequently in cases of angina pectoris. The surgical removal of the superior cervical ganglion would thus seem to be the most satisfactory method of attacking the problem; unusual complications doubtless would not occur.

The technic for the removal of the ganglion is that described by Coffey<sup>6</sup> in his work on angina pectoris: Incision is made through the sternocleidomastoid muscle; the carotid sheath is retracted forward and the ganglion lying mesially on the pre-spinal muscles is exposed. The connections of the ganglion are then severed, the ganglion is removed and the wound closed.

Although attempted in four persons, this procedure has been completed in only three. The results are reported at this time.

#### REPORTS OF CASES

CASE 1.—W. B., a man, aged 23, displayed natal duobranio-duobrachio-duoskelic cortical rigidity. The mentality was good. When first seen, the patient had a great deal of difficulty in walking and in the use of the hands. Speech was accom-

---

6. Coffey, Walter B.: Brown, Philip King, and Humber, John Davis: *Angina Pectoris*, New Orleans, A. J. Dickersen, 1927.

plished with tremendous effort and involved marked facial contortions. The extremities had been relieved of some of their difficulties by typical Royle procedures more than two years before. The patient was anxious to have the speech corrected. The foregoing procedure was proposed to him and was carried out in March and May, 1928.

Before the operation, the patient had difficulty in moving his jaw to the left, but could move it rather easily to the right. The tongue could be projected in the midline, but could not be put to the roof of his mouth: the lateral deviations were extremely ineffective. He had difficulty in pronouncing *h*, *k*, *s*, *w* and *x*, although he could speak them in an understandable manner. Speech was labored because it was difficult for the patient to pass from the formation of one sound to that of another.

After the removal of the left superior cervical ganglion, the patient smiled more on the left than on the right side, and his jaw could be deviated more easily and effectively to the right than to the left. The tongue moved more easily to the left than to the right and with a greater range. Speech seemed to be easier both objectively and subjectively; *c*, *q* and *x* were the letters pronounced most poorly.

A similar operation was done on the right side in May, 1928.

Examination on Sept. 21, 1928, showed that the patient smiled more effectively on the left than on the right. The jaw now moved equally well to both sides. The tongue also moved with about equal facility to both sides. Speech was much less labored than before the removal of the first ganglion, although the patient did not use his lips readily. It was thought that with a little training in speech the patient might form the labial sounds better. The greatest difficulty was with the letters *q* and *s*, particularly when these were combined with the vowels *i* and *o*. Speech was retarded when passing from monosyllables to duosyllables to trisyllables, as "use, useful, usefulness."

CASE 2.—B. R., a girl, aged 12 years, had natal right craniobranchiostic cortical rigidity. The mentality was high. The patient had a squint in the right eye. The jaw moved better to the right than to the left, and the tongue moved more easily to the left. She had attended school for a number of years and had had a great deal of training in speech which possibly accounted for her peculiar "cog-wheel" manner of speaking.

The difficulty lay in speed rather than in understandability, also in grimaces that accompanied speech. The speech was of the "cog-wheel" type, that is, an increase in the number of syllables caused greater and greater interruption between syllables.

On Feb. 2, 1928, a right lumbar ramisection was performed, and on June 14, a right superior cervical ganglionectomy. On September 21, the following conditions were observed: The patient smiled equally on the two sides and moved the jaw equally well to the two sides. The tongue, however, moved more easily to the left. In speaking there was practically an entire cessation of the facial contortions which were present before the operation and which involved not only the perioral, but the frontal, muscles. The most notable change in her speech was the almost total disappearance of the "cog-wheel" manner of speaking which was noted only in the use of trisyllabic words, whereas before operation it was noticeable in duosyllabic words. After the operation, the mother of the patient observed not only an improvement of speech, but a decided decrease in nervousness.

CASE 3.—J. Z., a girl, aged 9 years, had natal duocranio duobrachio-duoskelic cortical rigidity. The condition was severe. The child could neither sit nor stand; the use of the hands was greatly diminished, and the patient was so excitable that the slightest commotion completely upset her. Her speech, except for one or two

words, could scarcely be understood, even by the physiotherapist who had been training her. In spite of these difficulties, the child did not have a poor mentality. Attempts at speech were made by opening the mouth wide and uttering the sound without using the tongue, teeth or lips. During the fall and winter, both the lumbar and the brachial sympathetic connections were divided. Marked improvement in the ability to control the extremities followed. At present, the patient can stand alone for a few seconds. During the June following the first operation, both superior cervical ganglions were removed. There was a decided decrease in excitability and certain changes appeared in the speech. Before the operation, the patient had great difficulty in the use of *e* and *u* among the vowels and of *j*, *k*, *p*, *q* and *r* among the consonants, both alone and in combination. After the operation, there was distinct improvement in the ability to make these sounds. In testing the speech, each vowel was combined with every possible consonant in an initial and a following position, such as in "act" and "cat."

The results of the test indicated a decided drift from the impossible and difficult to the less degrees of difficulty. Of the consonants, *j* and *k* still remained difficult. Many words which the patient found impossible to utter before operation, such as

\* The difficulties were graded as follows: (1) impossible, (2) difficult, (3) slightly difficult and (4) normal.

† B indicates before operation.

‡ A indicates after operation.

"fi" and "ffi," "rebbe" and "rebellion," "useful" and "usefulness," she was able to pronounce after the operation, though with difficulty. I was much surprised one day after the operation to see the child wheel herself to the door and say distinctly, although throatily, "Hello, how are you?" After the operation, the patient used short sentences which could be readily understood by any one in the room. There was also an effort to talk with the use of the teeth, tongue and lips; these had not been used before. The mother remarked that "if the child was learning to walk as fast as she was learning to talk, she would soon be running."

The foregoing three cases represent three attempts to apply recently acquired observations concerning the sympathetic nervous system to the improvement of speech in patients with greatly increased muscle tone. They would seem to indicate that the muscles used in the formation of words and sounds are under the influence of the sympathetic nervous system to a certain degree, and that section of the sympathetic nerves in certain cases of dysphasia causes an improvement in speech. The cases are too few to be more than suggestive either of the exact difficulty that may be relieved or of the degree of improvement that may be anticipated.

# THE SCOPE OF NEUROLOGY\*

WILDER PENFIELD

Neurology today holds a position in the various medical centers of the world which varies from complete nonexistence to high and complex development. Invasion of the field of neurology by different types of clinicians, the rapid development of psychiatry, the late appearance of neurosurgery and the important recent advances in neurophysiology and neuro-anatomy, all help to account for this variability and demand a reconsideration of the scope of neurology.

The diseases of the nervous system present so many unsolved and intricate problems that in neurology, perhaps more than in any other branch of medicine, the *sine qua non* of advance is specialized study. This specialty, however, is often so subdivided that it ceases to be a specialty at all. In neuropathology lie the hidden clues which clinical advance must follow. Nevertheless, a knowledge of neuropathology, when present in a faculty of medicine, must often be sought in an isolated and little frequented corner of a general pathologic laboratory. Neurosurgery is often carried on as a side line by a busy general surgeon. The neurologist in the department of medicine, who is denied facility for study and treatment, may never have learned the possibilities of either science.

The neurologic clinic which is adequately prepared to meet the problems of the nervous system must ignore the artificial partitions that separate medicine, surgery and pathology. The pathologic department, which keeps neurologic autopsy material for exclusive study, the surgical department which insists that neurosurgery must be incidental to the work of general surgeons, and the medical department which is content to restrict the field of neurology to diagnosis, show the attitudes which form an almost insurmountable barrier to advance in the treatment of diseases of the nervous system.

A survey of neurology, neurosurgery and neuropathology as they are to be found in the various centers of learning today supports this view.

From the time that neurology first emerged as a specialty, it has suffered a progressive reduction in scope. In addition to its more and more clearly defined separation from psychiatry, there have been removed from the care of the neurologist patients with many of those ailments which are now susceptible of cure by modern methods. Thus, treatment for epidemic cerebrospinal meningitis is carried out in internal

---

\* From the Sub-Department of Neurological Surgery, McGill University.

medicine by those familiar with bacteriology and serum treatment in general. Poliomyelitis, and even syphilis of the central nervous system, to some extent have also become the province of the serologist. Orthopedic surgeons have largely taken over the treatment of patients with spastic paralysis and paralytic deformity. It is chiefly the diseases for which adequate therapy is lacking that are left undisputed in the province of neurology.

Tumors of the nervous system, because their diagnosis requires much specialized knowledge, have continued within the field of neurology; with the introduction of mechanical methods, however, such as Dandy's ventriculography, and with the increased efficiency of neurosurgeons, the neurologist has not infrequently been set aside even in these cases.

For the so-called functional neurologic cases, there has also been developed a therapy sometimes adequate and often inadequate, but nevertheless therapy. It includes psychoanalysis, faith healing, hypnosis, mental hygiene, gland therapy, etc. Some neurologists have entered this field and have lost touch with organic neurology. Some psychiatrists have entered the field without having an interest in organic neurology.

In view of the gradual dismemberment of the science, it is less surprising to find so few distinguished centers of clinical neurology in the world today. It cannot be denied that in such a clinic as the National Hospital of London, clinical teaching is at a high level. Also, the plans laid out by the University of Amsterdam for Brower's clinic seem to leave little to be desired for completeness. Such clinics are rare. On the continent of Europe, chairs created for combined teaching of neurology and psychiatry have come to be occupied by men who are interested in psychiatry rather than in organic neurology. At present, one searches in vain for great teachers of clinical neurology of the type of Erb and Oppenheim in Germany, and Charcot, Marie and Déjerne in France.

Neurology, when the term is taken in the broadest sense, has recently made great strides forward. Physiologists such as Sherrington, Magnus, Pavlov and Langley have made significant contributions. Neuroanatomy also, particularly in the Dutch school, is progressing rapidly. Neurohistology in the laboratories of Cajal and Vogt has opened up new horizons for the clinician.

New work in neuropathology has also gone far. It is significant that advances in this subject have rarely come from general pathologists, if one excepts Virchow, who must be considered an exception to any classification. It is true that useful technical methods have been provided by general pathologists, for example, Weigert and Mallory, but neuropathology has been carried forward by neurohistologists such as Achucarro and Del Rio Hortega, and by men trained and interested

in clinical neurology and psychiatry such as Alzheimer, Nissl, Spielmeier, Marie, Roussy, Wilson, Greenfield, Spiller and Bailey, and a host of neurologists whose pathologic studies were a part of their clinical work. The achievements of such men form the strongest argument for the concentration of neuropathologic material in neurologic and in psychiatric laboratories.

Striking recent development has taken place in the field of neurosurgery. Established as a specialty by Horsley, and elaborated and refined by Cushing, neurosurgery has come into its own in the United States. In general, this specialty has been carried out successfully by specializing surgeons who, thanks to their ever-increasing clinical experience, have gradually developed also into neurologists.

The need of neurology as a clinical entity is that it should carry out all of its own therapy. A purely diagnostic specialty cannot survive. Let it be granted that neurologists are the best equipped for antisyphilitic therapy, for the observation of encephalitis and for the treatment of psychoneurotic patients. That is not enough. Others can treat or observe patients with all of these conditions more or less satisfactorily.

Neurology must go a step further and embrace completely the therapy of its domain, including neurosurgery. Neurosurgery can be well done only by a surgeon who was in the beginning, or who became by experience, a neurologist.

Diagnosis and care in organic neurologic cases susceptible and not susceptible of surgical attack require the same clinical and pathologic training; that is, training in neurology, in neuro-anatomy, in surgery and in neuropathology. Obviously, neurosurgery can be done well only by a surgeon who devotes his entire time to that specialty. This fact is well demonstrated by the condition of neurosurgery in Europe at present, even in such large centers of population as Berlin and Vienna, where there are no specializing neurosurgeons and little neurosurgery is practiced.

On the other hand, exclusive and successful development of neurosurgery has demonstrated it to be invariably in close alliance with neurology. At Queen's Square, Horsley, as surgeon and neurophysiologist, created neurosurgery in a neurologic clinic with the help of neurologists of great vision such as Hughlings Jackson and Gowers. Other examples are Spiller and Frazier, the former a neurologist and neuropathologist, and the latter a surgeon who became a neurologist; Cushing, a neurophysiologist and surgeon who during his brilliant career as neurosurgeon has become a neurologist and neuropathologist, and Foerster, a professor of neurology and a distinguished neuro-anatomist, who has made of himself a neurosurgeon. However varied the approach, the outstanding neurosurgeons have come to have inter-

ests and insight in common with neurologists. In fact, they have become neurologists if they were not at the start.

The conclusion is not that all neurologists must perform operations (from a practical point of view, that is impossible, at present), but that the neurologists who perform operations and those who do not should be included in the same department, and should be given complete facilities for studying the disease entities which are their common problems.

This does not mean necessarily that isolation or absolute demarcation of such a department is necessary. On the contrary, when neurology is equipped with these facilities it should benefit by close association with general surgery in the operating room; with medicine, surgery and psychiatry in the clinic, and with pathology, medicine and psychiatry in the laboratory.

Only thus will neurology, coming into its own as a specialty, be able to grapple with its proper problems and do its part in the great undertaking that lies before the science of medicine today.

# ACQUIRED DIVERTICULA OF THE COLON

A STUDY OF THE END-RESULTS IN FORTY-FOUR CASES \*

FRANCIS C. NEWTON

Seventy years have elapsed since Cruveilhier<sup>1</sup> gave the medical world an anatomic description of the sacculations or outpocketings from the wall of the bowel which are known today as acquired diverticula. In 1853, Virchow<sup>2</sup> pointed out the presence of isolated, circumscribed, adhesive peritonitis of the colon, found most frequently at its various flexures. He was aware of some pathologic process which produced local inflammatory changes in the intestinal wall, in its coverings and in the mesentery and organs immediately surrounding it. He gave a perfect description of peridiverticulitis, but failed to appreciate what lay behind the condition he was describing. Windsheid,<sup>3</sup> in 1889, added further description of similar cases, but it was not till Graser,<sup>4</sup> toward the close of the century (1899), demonstrated the association of acquired diverticula with these pathologic changes that a clear understanding of the condition was attained. Since then many other writers, notably Telling,<sup>5</sup> Beer,<sup>6</sup> Moynihan,<sup>7</sup> W. J. Mayo,<sup>8</sup> McGrath,<sup>9</sup> Gant,<sup>10</sup> Wilson<sup>11</sup> and Miller,<sup>12</sup> aided by the x-rays, have added materially to the knowledge of this pathologic condition, some instances of which are apparently innocuous, while others present problems of the gravest diagnostic and surgical difficulty.

Roentgen Observations	Laboratory Observations	Treatment	Coincident Pathologic Processes	Complications	Result	Autopsy
Not done	Urine, slight trace of albumin; white blood cells, 11,900; hemoglobin, 85%; temperature, 101 F.	Suture of perforation in sigmoid; drainage of peritonitis; transverse colostomy	None	None	Died in 24 hours of peritonitis	Shows B. coli peritonitis; multiple diverticula in sigmoid
Not done	Urine, slight trace of sugar; granular and hyaline casts; white blood cells, 24,000; hemoglobin, 75%; red blood cells, 5,100,000; temperature, 100 F.	Drainage of peritonitis	None	.....	Died 3 days later of peritonitis	
Spastic area 2 cm. in length in lower sigmoid; numerous diverticula above this point; second area of spasm in upper sigmoid	Urine, slight trace of albumin; few red and white cells and hyaline casts; white blood cells, 10,200; temperature, 101 F.	Transverse colostomy	Auricular fibrillation	None	Fistula still draining from pinpoint opening; occasional blood by enema; pelvic examination shows freely movable nontender mass; general condition improved; has occasional attacks of fibrillation	
Persistent narrowing and spasm in sigmoid	Urine, negative; white blood cells, 12,000; hemoglobin, 90%; temperature, normal	Drainage of pelvic abscess	Varicose veins; arthritis	.....	Reports completely relieved; "well"	
Diverticula in duodenum, small bowel, descending colon and sigmoid	Urine, slight trace of albumin and red cells; hemoglobin, 90%; white blood cells, 13,000; temperature, 100 F.	Palliative	None	None	Completely relieved; "feeling fine"	
Single diverticulum in lower part of descending colon	Urine, negative; phthalein, 60%; hemoglobin, 93%; white blood cells, 9,200	Palliative	Chronic myocarditis	None	"Able to be up and around"	
Duodenal ulcer; three to five diverticula in sigmoid	Urine, negative; Wassermann test, negative; white blood cells, 6,200; red blood cells, 4,900,000; hemoglobin, 85%; temperature, normal	None; no indication to diverticulitis	Ulcer of duodenum	None	On later hospital entry posterior gastro-enterostomy done; symptoms unchanged	
Eight to ten diverticula in middle third of descending colon	Urine, negative; hemoglobin, 80%; white blood cells, 8,900; temperature, normal	None	None	None	Untraced	
Single diverticulum in ascending colon; sigmoid and descending colon quite irritable	Urine, negative; phthalein, 50%; Wassermann test, negative; hemoglobin, 95%; white blood cells, 9,500; red blood cells, 5,392,000	Palliative	None	None	Improved	
Multiple diverticula in sigmoid and descending colon; stone in left kidney	Urine, slightest possible trace of albumin; occasional white cells; phthalein, 60%; white blood cells, 10,800; hemoglobin, 80%; temperature, normal	Left pyelotomy for nephrolithiasis	Silent stone in kidney	None	"In fine condition"; no complaint	
Not done	Urine, slight trace of albumin; Wassermann test, negative; phthalein, 25%; hemoglobin, 95%; red blood cells, 3,880,000; white blood cells, 12,800; temperature, 100 F.; also in urine, rare white cells and hyaline casts	Not treated (from standpoint of diverticula)	Chronic myocarditis; hypertension; auricular fibrillation; nephritis; generalized arterial sclerosis; cholelithiasis; infarct of lung	.....	Died of coincident pathologic process	Condition in sigmoid first discovered at autopsy

TABLE 1.—*Report of*

Case	Ward or Private, Age, Sex	Color; Married, Single, Widowed	Variety of Lesion	Stool Examination	Number of Diverticula, Location	Symptoms and Signs
L. G. Case 23	Ward 6S Male	White Married	Group 1	Normal	Multiple; sigmoid	Three months of loss of weight and appetite; attacks of vomiting following taking food; sense of fullness in the abdomen
A. E. R. Case 24	Ward 5S Female	White Widow	Group 2	Normal	Multiple; sigmoid and descending colon	Recurrent attacks of generalized abdominal pain, chiefly in lower left quadrant; nausea and vomiting; occasional blood in stools (hemorrhoids present); marked constipation; questionable mass
E. A. H. Case 25	Private 53 Female	White Widow	Group 2	Much mucus	Multiple; throughout whole bowel, most marked in sigmoid	Abdominal discomfort relieved by flatus and discharge of soft mucous stools, for one year
A. M. T. Case 26	Ward 4S Female	White Widow	Group 3	Normal	One; sigmoid	Shooting pains in lower left quadrant; diarrhea of eight days' duration; previous (4 years ago) diagnosis of chronic spastic colitis; extreme tenderness and voluntary spasm in lower left quadrant and palpable mass by abdominal and pelvic examinations
C. S. Case 27	Ward 63 Female	White Widow	Group 1	Normal	Multiple; entire colon	Negative as far as diverticula are concerned
J. N. Case 28	Private 60 Female	White Widow	Group 4	Negative	Multiple; sigmoid	Grumbling pain in lower part of abdomen of from four to five years' duration, with some symptoms of obstruction; dysuria; constipation; mass palpable by rectum in pouch of Douglas
A. T. Case 29	Ward 60 Female	White Married	Group 3	Negative	One; cecum	Pain in right lower quadrant; tenderness, vomiting, constipation
H. M. Case 30	Private 67 Male	White Married	Group 3	Negative	One; sigmoid	Poor appetite and constipation for years; only acute symptom, cloudy urine
C. W. B. Case 31	Ward 65 Male	White Married	Group 3	Negative	Undetermined; sigmoid	Persistent diarrhea for one year; severe steady pain over whole lower part of abdomen, particularly before admission to the hospital, enemas giving no relief; tense tympanites in left part of abdomen

Roentgen Observations	Laboratory Observations	Treatment	Coincident Pathologic Processes	Complications	Result	Autopsy
Multiple small diverticula in the sigmoid	Wassermann test, negative; gastric analysis, achylia; phthalein, 0; urine, trace of albumin; fixed spastic gravity; numerous white cells; many granular casts; hemoglobin, 65%; red blood cells, 3,470,000; white blood cells, 5,880; temperature, 99 F	Not treated	Chronic nephritis; red edema; uraemia		Died 2 weeks after entry to hospital of coincident pathologic process	Autopsy not done
Sigmoid spastic, irritable and narrow; multiple diverticula decreasing toward flexure of descending colon	Urine, negative; white blood cells, 6,600; hemoglobin, 80%; red blood cells, 1,300,000; temperature, 99 F	Palliative	Hypertension	None	One year after discharge from hospital had a severe attack with blood, pain, nausea, constipation and obstruction; finds that a tablespoonful of mineral oil relieves bowel difficulty	
Multiple diverticula throughout bowel most marked in sigmoid	Wassermann test, negative; urine, negative; hemoglobin, 70%; red blood cells, 4,600,000; white blood cells, 7,000; temperature, 99 F	Palliative	Diaphragmatic hernia of stomach; cholelithiasis; nephrolithiasis		Relieved of symptoms	
Not done	Wassermann test, negative; urine, numerous white cells, rare hyaline casts; hemoglobin, 85%; red blood cells, 4,900,000; white blood cells, 18,000; also trace of sugar in urine	Operative drainage of abscess located posterior to uterus, along side of dilated sigmoid	Mild diabetes	None	Reexamination by enema showed the colon to fill completely and well, careful search failed to show any evidence of diverticula; a film after evacuation shows almost complete emptying; impression, normal colon	
Multiple diverticula in entire colon	Wassermann test, negative; urine, slight trace of albumin, hyaline and granular casts, few white cells, white blood cells, 13,230; red blood cells, 4,300,000; hemoglobin, 80%; temperature, 102 F	None from standpoint of diverticulitis	Acute bronchitis; chronic arthritis	None	Improved, untraced	
Not done	Urine, negative; white blood cells, 7,100; hemoglobin, 85%; temperature, 100 F	Operative 1 drainage of pelvic abscess, 2 resection of pelvic colon, 3 colostomy, 4 secondary repair of recto sigmoid anastomosis, 5 closure of colostomy			Untraced	
Not done	Urine, normal, hemoglobin, 85%; white blood cells, 13,800; temperature, 99 F.	Excision of diverticula; appendectomy	None	None	Well	
Fistula between sigmoid and bladder	Badly infected urine; phthalein, 35%; white blood cells, 33,000; Wassermann test, negative; temperature, 103 F.	Operative 1 colostomy; 2 closure of fistula of bladder; partial resection of sigmoid; 3 closure of colostomy	Pyelitis; cystitis		Died 2 years after discharge, of urinary infection	
Not done	Urine, trace of albumin, granular casts; white blood cells, 20,000; hemoglobin, 80%	Colostomy for diverticulitis and gangrene of sigmoid	None	Peritonitis	Died 2 days later	

TABLE 1.—*Report of*

Case	Ward or Private, Age, Sex	Color; Married, Single, Widowed	Variety of Lesion	Stool Examination	Number of Diverticula, Location	Symptoms and Signs
C. R. R. Case 32	Ward 43 Male	White Married	Group 3	Negative	Multiple; sigmoid	Nausea; vomiting; general abdominal pain, following marked constipation and diarrhea alternately; signs of general peritonitis
J. E. L. Case 33	Ward 34 Female	White Married	Group 3	Negative	One or more; sigmoid	Pain in lower part of abdomen for two months, particularly in lower left quadrant; painful micturition; abdominal tenderness over lower left quadrant; pelvic examination shows hard, firm mass in left side; moderately tender
P. Y. Case 34	Ward 55 Male	Colored Separated	Group 3	Mucoid, grayish	Undetermined; sigmoid	Abdominal pain and distention of six months' duration; nausea and vomiting; loss of weight; marked dullness to percussion in left flank with tenderness; mass palpable; scrotal extension
E. A. W. Case 35	Ward 46 Female	White Single	Group 2	Negative	Multiple in descending colon; one in ascending colon	Hysterectomy one year previous for soreness and pain in lower part of abdomen with persistent constipation; tenderness in the abdomen of three months' duration with severe colicky pain in both lower quadrants before admission; slight nausea
H. M. L. Case 36	Ward 30 Male	White Married	Group 3	Negative	Multiple; sigmoid	Attacks of acute indigestion always associated with dietetic indiscretions; constipation; acute sharp pain before admission to the hospital, without radiation to the abdomen; abdominal tenderness with vomiting
M. C. Case 37	Private 64 Male	White Married	Group 3	Negative	Multiple; sigmoid flexure	Long standing urinary infection with vesicosisigmoid fistula
M. L. W. Case 38	Ward 70 Female	White Widow	Group 2	Negative	Multiple; colon	Constipation for 25 years; attack of indigestion four years ago; has had bleeding piles for seven years
W. A. F. Case 39	Ward 66 Male	White Married	Group 1	Negative	Undetermined; sigmoid flexure of colon	Negative
A. M. L. Case 40	Private 50 Male	White Married	Group 2	Negative	Undetermined; descending colon	Negative; fleeting attacks of abdominal pain
M. K. B. Case 41	Ward 35 Female	White Married	Group 1	Negative	Multiple; colon	Negative
A. D. F. Case 42	Private 62 Female	White Separated	Group 2	Negative	Several; sigmoid	Negative; attack of abdominal pain with diarrhea
A. H. Case 43	Private 48 Male	White Married	Group 3	Negative	Two; sigmoid	Generalized abdominal pain; localized pain in lower left quadrant, growing cramplike; constipation; high temperature
M. M. Case 44	Private 64 Female	White Married	Group 5	Gross blood and pus	Multiple; upper sigmoid, lower descending colon	Pain in lower left quadrant with constipation, nausea and vomiting, pain growing steadily more severe; blood in stools

Cases—Continued

Roentgen Observations	Laboratory Observations	Treatment	Coincident Pathologic Processes	Complications	Result	Autopsy
Not done	White blood cells, 16,000; urine, not done; temperature, 103 F	Abdominal drainage for general peritonitis from diverticulum in sigmoid	None	Peritonitis	Died	
Not done	Urine, slight trace of albumin, pus, red and white cells; white blood cells, 17,000; hemoglobin, 90%; temperature, 100 F	Closure of perforated diverticulum of sigmoid; bilateral salpingectomy	None	Pelvic peritonitis	No recurrence; well	
Not done	Urine, pus and white cells, occasional casts, slight trace of albumin; white blood cells, 19,000; temperature, 101 F	Drainage of pelvic abscess	None	Post-operative fecal fistula	No recurrence; well	
One diverticulum in ascending colon; many in descending	Urine, white cells, white blood cells, 7,800; hemoglobin, 75%	Palliative	None	None	Untraced	
Irregularity and spasm in sigmoid flexure	Urine, many hyaline and granular casts, few white cells, white blood cells, 15,000; hemoglobin, 85%; temperature, 99 F	Drainage of pelvic abscess	None	None	No recurrence; well	
Multiple diverticula in sigmoid	Urine, many white cells and trace of albumin, phthalein, 55%; hemoglobin, 90%; white blood cells, 11,200; temperature, 99 F	Operative: 1. resection of fistula; colostomy; 2. resection of sigmoid; repair of fistula; 3. closure of colostomy	None	None	Died 2 years after discharge of heart trouble and edema of lungs	
Not done	Wassermann test, negative; urine, negative; hemoglobin, 75%; red blood cells, 4,200,000; white blood cells, 4,800; temperature, normal	Not treated	Auricular fibrillation; pulmonary infarction; renal infarction; leiomyoma of uterus, cholelithiasis	None	Died 10 days after admission of coincident pathologic process	Coincident pathologic processes revealed at autopsy
Diverticulitis involving sigmoid flexure of the colon	Wassermann test, negative; urine, negative; hemoglobin, 65%; red blood cells, 5,376,000; white blood cells, 7,550; temperature, normal	Not treated	Emphysema	None	Untraced	
Three round, isolated, movable masses in descending colon; may be residue in diverticula	Wassermann test, negative; phthalein, 52%; urine, rare hyaline casts, considerable mucus; hemoglobin, 100%; white blood cells, 9,000	Not treated	Hypochlohydria	...	"Condition has been good"	
Multiple diverticula in colon	Wassermann test, negative; urine, negative; hemoglobin, 75%; red blood cells, 4,920,000; white blood cells, 9,550; temperature, normal	Not treated	Psychoneurosis; chronic cystitis	None	Condition unchanged	
Irritable descending colon; several diverticula in sigmoid	Phthalein, 60%; urine, negative; white blood cells, 7,100; red blood cells, 4,200,000; temperature, normal	Palliative	None	None	Very well; no bowel trouble; no symptoms	
Two diverticula in ascending colon	Urine, rare white cells; hemoglobin, 80%; temperature, 102 F; white blood cells, 21,000	Operative: drainage of abscess and cecostomy	Peritonitis; fistula, fecal	None	Improved; fistula drains occasionally	
Multiple diverticula in upper sigmoid and lower descending colon; mass medial to lower end of descending colon	Urine, rare white cells; hemoglobin, 80%; white blood cells, 14,700; temperature, normal	Operative: cecostomy; drainage of abscess; transverse colostomy	Carcinoma of plicose loop of colon	Infection of abdominal wall around sinus	Died of carcinoma months after leaving hospital	

The forty-four cases reported here represent all the proved instances of diverticula to be found in 56,000 patients admitted to the hospital over a period of fourteen years. They are presented in such a way as to render comparison and analysis of symptoms, treatment and results as clearly as possible.

In the forty-four proved cases in this record, seventeen of the patients were admitted to the medical service and twenty-seven to the surgical service. They are to be found about as evenly distributed among the better class as the poor (twenty-five charity patients and nineteen private patients). There is a somewhat larger percentage of cases in females than is usually recorded. Most observers find them twice as frequently in males as in females. Twenty-five of these cases were in males and nineteen in females. The disease may occur in any decade of life, but is commonest between the ages of 40 and 60. The youngest patient in this series was 12 years old, and the oldest, 77. Twenty-one of the cases (the majority) occurred in the sixth decade of life, and nine (the second largest number) in the fifth decade.

Acquired diverticula of the large bowel are found in the ascending and transverse colon, much more frequently in the descending colon, commonly in the sigmoid, and extremely rarely in the rectum. In this series, twenty-five were in the sigmoid and twelve in the descending colon. Eight cases showed them distributed throughout the entire colon; one case showed the disease confined to the ascending colon and one to the cecum.

Numerous ways of classifying intestinal diverticula have been proposed. I have adopted the one which combines the clinical picture with the pathologic changes as being the best suited to a general study of this kind. Five groupings are made:

Group 1: Cases showing no clinical symptoms (ten).

Group 2: Cases showing symptoms but no abscess, fistula or peritonitis (eighteen).

Group 3: Cases showing peridiverticulitis (abscess, fistula and peritonitis included) (thirteen).

Group 4: Cases showing peridiverticulitis plus obstruction (two).

Group 5: Cases showing coincident carcinoma (one).

In the cases in groups 2, 3 and 4, one or all of the following pathologic conditions may be found: chronic extramucosal inflammation; adhesions to adjacent structures; perforation resulting in general peritonitis; acute gangrenous inflammation of sigmoid around the diverticula; local abscess formation; fistulas between the seat of the trouble and neighboring organs (notably in bladder); chronic mesenteritis, with thickening, kinks and adhesions; and metastatic suppuration of the liver. Group 5 includes only those cases in which there is an intestinal carcinoma within or near the diverticula. The diagnosis in symptom-

less cases is made by the roentgen examination. Here their presence is chiefly important from the standpoint of what may develop later.

A perusal of the histories of the cases in the other four groups shows a far more characteristic story and clinical observations than is usually believed true. There may be a story of disability which has been present for years. Usually, however, unless the condition is recognized and the patient treated, the past history covers a rather arbitrary period of two years. Again, there may be no symptoms what-

Fig. 1 (group 1, case 29).—Multiple silent diverticula throughout entire colon.

ever until the onset of acute trouble just before admission to the hospital. In cases of long-standing chronic trouble, one finds a story of vague discomfort in the abdomen, indigestion, gas and increasing but not persistent constipation alternating with diarrhea, occasional cramps and a subnormal feeling. Loss of weight is not a characteristic symptom. With the onset of an acute condition, the picture changes rapidly, and the differential diagnosis becomes difficult. There is a moderately high fever, leukocytosis, constipation or profuse diarrhea, diffuse tenderness or localized spasm and a palpable mass. Unless there is an

obstruction, vomiting is absent. Blood that can be observed macroscopically in the stool is rare; even that observed microscopically, as found by benzidine or guaiac test, is not common. In thirty-three cases, blood was not found by any test. In five, there was a positive benzidine and in one a positive guaiac test. The highest white cell count was 39,000 with the average leukocytosis about 18,000.

In the first two groups of cases, i.e., those in which there were no symptoms and those in which there were symptoms but no peridiver-

Fig. 2 (group 2, case 21) —Diverticula in descending colon and sigmoid; left kidney stone

iculitis, the diagnosis may be made by the roentgen examination, depending on the keenness with which the fluoroscopic examination is made and the plates are read. Small diverticula, few in number, may appear to be only bits of retained barium sulphate. Frequently, however, there is an accompanying spasm of the bowel in the affected area which calls attention to the presence of a pathologic process. In such cases, if one looks carefully for diverticula they are usually visualized. In acute cases, the differential diagnosis is complicated. The two lesions

most commonly confused with diverticulitis are appendicitis, either in its normal position or left-sided, and carcinoma. Tuberculosis, intestinal obstruction, so-called chronic sigmoiditis, fecal impaction, foreign bodies, disease of the adnexa, tumor of the bladder, etc., must be ruled out if one is to differentiate accurately. Roentgen examination in acute cases by means of a barium sulphate enema as a means of making a diagnosis is extremely dangerous unless wisely used. The danger of perforation under such circumstances is very real. In one case in this series, the

Fig. 3 (group 2, case 42).—Irritable descending colon; several diverticula in sigmoid; abdominal pain and diarrhea; improvement under medical treatment.

condition was converted into peritonitis with a fatal termination by this means.

No more puzzling diagnostic problem can be encountered than is presented by those cases in which a carcinoma exists with the diverticulitis. Fortunately these cases are comparatively rare, although some writers have found the incidence running as high as 25 per cent (McGrath<sup>9</sup>). In this series, however, only one case fell in the last group-

ing. The preoperative diagnosis under such circumstances is no more difficult as far as the diverticulitis is concerned, but is extremely so from the standpoint of the double diagnosis. Even at the operating table, the picture is frequently almost impossible to recognize. The desirability of early and wide resection when carcinoma exists has all too often led to radical and fatal treatment for the diverticulitis. The operative mortality could be materially reduced if the lesion could be segregated from the carcinoma and resection delayed. Even frozen

Fig. 4 (group 2, case 16).—Diverticulitis of sigmoid; pain, tenderness, nausea and left lower abdominal spasm, relieved by medical treatment

sections are unreliable in cases of doubt, because so frequently it is impossible to tell from which part of the whole mass to cut tissue for pathologic examination. So many explanations of the etiology of this disease have been offered that one may be excused for looking with some suspicion on any of them. Various writers have attributed these false outpocketings of the intestinal walls to inherited weakness of the wall, gas or fecal distention, advancing age with weakened musculature, wasting disease such as cancer and tuberculosis, colitis of long standing.

intestinal atrophy, hemorrhagic mesenteric infarcts, worms, obstruction, dilated glands, enlarged vessel openings in the bowel wall and to the normal weak areas about the appendices epiploicae of the large bowel. The majority of observers agree that the latter fact most often explains the beginning of trouble.

Successful treatment in any case of colonic diverticula can be carried out only with a clear understanding of the course of the disease and its possible complications. Too little attention has been given to the seem-

Fig. 5 (group 2, case 2).—Multiple diverticula throughout entire colon; alternate attacks of diarrhea and constipation with abdominal pain.

ingly innocuous case of diverticulosis in which no symptoms are presented. Whenever the condition is discovered, it calls for careful supervision and attention to colonic hygiene. The establishment of regular and spontaneous evacuation looking toward the prevention of inspissated bits of feces becoming lodged in the diverticula should be emphasized. Frequent efforts to change or improve the intestinal flora reduce the chance of infection within these pouches. Mineral oil taken regularly will help to prevent constipation and consequent straining at

stool with its very undesirable increase in intracolonic pressure. For the same reason, high pressure enemas are never to be used. It should be pointed out that any case which is being carried along under this palliative or prophylactic treatment should be considered a possible surgical emergency at any moment. Even with the appearance of signs of inflammation and a possible tender mass, conservative measures may still be efficacious, and the acute attack overcome. Warm enemas, oils, hot applications, morphine, atropine, liquid diet and bismuth subnitrate

Fig. 6 (group 3, case 37).—Sigmoidal diverticulitis with fistula of the bladder; long standing urinary infection cause of hospital entry; relieved by resection.

are helpful. It must be recognized that surgical intervention in this stage, before actual abscess formation, can do very little good. The risk of spreading infection by resection at this time is too great, and no good can be accomplished by simple drainage before suppuration has begun. Experience and good judgment may often save either an unnecessary surgical procedure or an operative catastrophe. Some writers advocate operation at the first sign of inflammation as in appendicitis. The presence of fat tabs and a thickened short mesentery in the lower colon,

however, differs so tremendously from the situation about the cecum that it is often well nigh impossible to locate a focus of inflammation which would allow of a procedure analogous to appendectomy. Once true diverticulitis has appeared, however, plans for operation at a suitable time should be laid. Recurrence of trouble is almost certain, so that, provided the lesion as demonstrated by roentgen examination will lend itself to resection, this should be carried out. If the disease is spread over a wide area, a colostomy or anastomosis around the affected

Fig. 7 (group 3, case 43).—Diverticulitis and peridiverticulitis with large abscess palpable in left lower quadrant; improved by surgical drainage and colostomy.

bowel may be the only feasible solution of the problem. In the more serious cases complicated by fistula, abscess or local peritonitis, simple drainage of the infected area is the only permissible procedure. A colostomy should, however, always accompany the drainage. The more completely the fecal stream is diverted, the better chance the patient has of recovering from the abscess and its surrounding conditions. In cases of obstruction, colostomy is, of course, imperative. With complete subsidence of infection, resection may be carried out. This must be

delayed usually for weeks or even months, or until all infection has subsided. Whenever the adhesions about the diseased bowel can be freed, a Mikulicz multiple-stage operation is the safest. Unfortunately, only a few patients can be so treated, leaving only resection and anastomosis or a short-circuiting operation possible, depending on the amount of colon involved.

Of the forty-four cases included in this report, thirty-nine have been reviewed from the standpoint of their final result. No records are

Fig. 8 (group 4, case 14) —Diverticulitis and peridiverticulitis of sigmoid with palpable mass in left lower quadrant, abdominal pain and tenderness, improved by drainage and colostomy

included, other than those of fatal cases, of less than two years' standing, while some cover a period of over ten years. The following graphic representations present the results in the light of the method employed in the treatment, and from the point of view of the symptoms and pathologic process when the patient was admitted to the hospital.

It will be seen from the foregoing figures that in this small series of cases which have been followed up there are thirteen in which treatment was not given, either because of the purely incidental nature of the con-

dition, or because of the patient's refusal to follow directions. Today eight of these patients are in exactly the same condition as they were when in the hospital, and five have died of other trouble such as apoplexy, insanity, cardiorenal disease or diabetes. The question may be raised whether even silent diverticula may not have had some part in the production of pulmonary infarcts and cardiorenal disease as well as in the production of a fatal termination after two and one-half years in a case complicated by diabetes. The results were uniformly good in the

Fig. 9 (group 5, case 44).—Diverticulitis and peridiverticulitis of descending colon and sigmoid with abscess and obstruction and adjacent nonobstructing carcinoma in ptosed loop of transverse colon; abscess from diverticula drained; death from carcinomatosis.

ten patients who, presenting vague abdominal symptoms, received adequate dietary treatment and supervision. Eight are definitely improved and only two have died (of apoplexy and insanity). Of those who received operative treatment, seven may be considered well, these being the only cases in the entire series with this result. All of these patients had the diseased portion of the colon removed or an abscess drained, and are now in perfect health as far as can be determined. Four

patients, all with serious complications, abscess, obstruction or fistula, were definitely improved. Three have remained so to the present time. One died three years later of a urinary infection, which is not surprising in view of the presence of a fistula of the bladder at the time of operation. Four patients died postoperatively. All of these had spreading peritonitis. All but one of the sixteen patients operated on presented the picture of neglected diverticulitis, and were most serious surgical risks when operated on. The one patient who had carcinoma as well as diverticulitis was a hopeless problem from the start, having a rapidly growing tumor close to a diverticulitis and peridiverticulitis of the sigmoid with abscess formation.

TABLE 2.—*Results Grouped According to Treatment*

	Total	Died	Improved	Well	No Change	Died of Other Pathologic Processes
Operated on.....	16	5	2	7	0	2
Medically treated.....	10	0	8	0	0	2
Untreated.....	13	0	0	0	8	5
	39	5	10	7	8	9

TABLE 3.—*Results Grouped According to Pathologic Process*

	Died	Improved	Well	No Change	Died of Other Pathologic Processes
Group 1 (symptomless).....	0	0	0	4	3
Group 2	0	8	1	4	4
Group 3	4	1	6	0	2
Group 4	0	1	0	0	0
Group 5 (with carcinoma).....	1	0	0	0	0
	5	10	7	8	9

Five patients of the total forty-four in the entire series could not be traced. They were either symptomless while in the hospital, or refused treatment offered them because of the mildness of their condition.

#### CONCLUSIONS

Acquired diverticula of the colon may give rise to such serious complications that even their incidental discovery calls for careful prophylactic measures and medical supervision. If symptoms cease under this regimen, it is fair to conclude that the more dangerous later developments may be avoided. If, however, symptoms continue or recur, resection, wherever possible, should be carried out, as this presents the only avenue to a permanent cure. When the condition is not recognized early, or treatment must necessarily be undertaken during the later stages of the disease, such as abscess, fistula or obstruction, conservative surgical treatment, i.e., drainage plus colostomy, is the only indication in the beginning, to be followed by removal or short-circuiting of the diseased bowel at another time.

# INTRACRANIAL SARCOMATOUS TUMORS OF LEPTOMENINGEAL ORIGIN \*

PERCIVAL BAILEY

Sacoma, autrement dit Fungus, est  
vne excroissance de chair qui vient  
de l'aliment propre de la partie où  
elle naist.—*Ambroise Paré.*

During the course of the last century the diagnosis of sarcoma of the brain was often made, and if the term be understood in its original sense, namely, to designate a soft, fleshlike (*σάρξ*, flesh), rapidly growing, cellular tumor, this diagnosis was probably correct; but as the use of the term began to be restricted to the rapidly growing tumors of mesodermal origin, it was soon felt that for cellular tumors of the brain it was a misnomer, since they were certainly of neuroglial nature and hence of ectodermal origin. Consequently, they came to be called gliosarcomas, but ere long this term also was superseded by that of glioblastoma or spongioblastoma, and the existence of a true malignant mesodermal tumor of the brain was doubted.

Yet at first thought one would say that there is not lacking in the intracranial cavity, even in the brain itself, tissue from which sarcomas, understood in the foregoing limited sense, might presumably arise. The dura mater is generally regarded as a structure of mesodermal origin. The leptomeninges also were conceded to be of similar embryologic derivation until of recent years, when Oberling proposed, on evidence derived from studies of microscopic changes alone, that the meningo-blasts which formed the leptomeninges had an origin similar to that of the cells of the sheath of Schwann, being therefore neuro-ectodermal. He made some fragmentary embryologic observations, but it remained for Harvey and Burr, who had come to the same opinion from different premises, to make a thorough embryologic and experimental study which seemed to prove that the leptomeninges originated from the neural crest in the same manner as the cells of the sheath of Schwann.

The conception of the neuro-ectodermal origin of these structures led Lhermitte and Leroux, and later, Masson, to describe the neurinomas of the peripheral nerves under the name of "gliomes périphériques," and although Masson did not go so far as to call the ordinary meningiomas "gliomes méningés," still he made it evident that he agreed with Oberling in considering them, as well as the acoustic neurinomas, to be essentially of a gliomatous nature. This conception has recently been

---

\* From the Surgical Clinic of Dr. Harvey Cushing, Peter Bent Brigham Hospital, Boston.

adopted by Martin, Dechaume and Puig. Occasionally a tumor of the meninges occurs that by its microscopic structure seems to support this hypothesis of the neuro-ectodermal origin of the leptomeninx. Such a tumor was described by Roussy, Cornil and Leroux.

I have never seen such a tumor, and it must not be forgotten that the finding of fibrillae stained with methods for neuroglial fibrillae is not sufficient to demonstrate the neuro-ectodermal nature of a tumor. Such fibrillae may be fibroglia or even epithelial fibrillae. Nevertheless the close relationship of the meningioma, the acoustic neurinoma and the peripheral neurinomas is clearly shown also by their occasional simultaneous occurrence in cases of von Recklinghausen's disease, as Oberling pointed out.

Add to all this the fact that the sheaths of cells which surround the blood vessels of the brain are of leptomeningeal origin and that tumors adhering to the dura mater in all probability arise from leptomeningeal cells which have penetrated into this membrane (M. B. Schmitt), and the possibility of development of a true sarcoma in the intracranial cavity seems to vanish completely.

Logical though this neuro-ectodermal theory seems to be, one cannot help feeling that it is somewhat overschematic. There are not lacking embryologists who describe the derivation of mesenchyme from the ectoderm during embryonic life. This derivation can even be followed in tumors according to certain pathologists (Masson and Peyron, Kromeyer, etc.). I have followed the origin of collagenic fibrils from epithelial cells in suprasellar epitheliomas. The same origin can be found in many lower animals (Delaney).

Moreover, it will not do to push the histogenetic classification of tumors too far lest they all become epitheliomas. Masson remarked that it is not the blastodermic origin of a cell which characterizes it, but solely its histofunctional differentiation; for example, the cortex of the suprarenal gland is of mesodermal origin but becomes glandular epithelium, and when undergoing malignant change produces a carcinoma (Peyron), not a sarcoma. On the other hand, a cell which produces collagen may have epithelial ancestors but is itself a connective tissue cell; it is a matter of definition. By this admission, Masson condemned his own term of "*gliome périphérique*," for certainly the leptomeningeal cells and cells of the sheath of Schwann in the fully developed condition are more nearly allied structurally to connective tissue derivatives than to the ordinary ectodermal derivatives. Nageotte has shown how the cells of the sheath of Schwann form collagen, and it is well known that the leptomeningeal cells form reticulin, collagen and elastin (Key and Retzius).

The vast majority of the tumors of the leptomeninges also reproduce the structure of tumors of the connective tissues rather than that of

gliomas. Prym, in 1914, stated that the cells of dural endotheliomas were connective tissue cells because they formed the intercellular substances of connective tissue. Mallory, after a detailed study of the microscopic structure of the component cells of meningiomas, concluded that they were fibroblasts. Penfield has recently maintained that the cells of acoustic and of peripheral neurinomas are also fibroblasts and speaks of meningeal, acoustic and peripheral fibroblastomas. Rhoads and van Wagenen confirmed his opinion concerning the acoustic neurinomas.

The conception of the fibroblastic nature of these tumors seems also to be overschematized, although not so much so as the conception of their glial nature. Their structure differs both from that of glioblastomas and from that of the ordinary fibroblastomas arising from the other organs of the body, usually resembling more closely endothelioblastomas growing without formation of lumina. Of the intercellular substances formed by fibroblasts, reticulin is scanty in the meningiomas; collagen is found only around the vessels and in degenerated areas; fibroglia is rarely seen and elastin only around large blood vessels in most cases.

Brault has remarked that "every connective-tissue cell is by tendency angioplastic. It is practically impossible in histology to separate the two terms: connective tissue and vascular tissue. This opinion is largely confirmed by the study of inflammation of the serous membranes, of the formation of new vessels in obliterating arteritis and of thromboses." Endothelial cells form collagen and elastin in the intima of the developing aorta (Aschoff), in the intima of transplanted veins (Enderlen and Borst) and in the intima of the vessels of racemose angiomas (Cushing and Bailey). The fact that in rare instances the cells of a meningioma form fibroglia, collagen and elastin does not prove, therefore, that they are not endothelial cells. Even in tissue cultures, endothelial cells may transform themselves into fibroblasts (Maximow). In an endothelioma, the mesenchymal cells decrease in rapidity of growth without forming intercellular substance, but with a tendency to apply themselves to surfaces (if there is no surface, they wrap around each other); this is what makes an endothelioma, the endothelial cells having few structural characteristics by which they may be recognized (see Hortega). If embryonic mesenchymal cells slow up in growth and at the same time form intercellular substances, a fibroma, chondroma, etc., results.

Thus the term to be used for meningeal tumors is again a matter of definition. The fact that a few of the cells form fibroglia, elastin, collagen or reticulin does not change the other fact that the vast majority of the cells are endothelial, or "mesothelial," at any rate not typical fibroblasts. For the moment it might be well to include *them* and the neurinomas under some noncommittal term, such as *neurolophomas* as

Harvey and Burr suggested, or *chitoncuromes* from *χιτών* (tunic) as used by Martin, Dechaume and Ping, or perhaps *lophostegomas* from *λόφη* (crest) and *στέγω* (to cover) which would emphasize their common origin from the neural crest and their common function as covering cells for the nervous system.

Whatever may prove in the final analysis to be their exact nature, the rapidly growing tumors described in the present communication I believe to have arisen from the leptomeninges or its derivatives, and consider it advisable to call them sarcomas, for their structure differs considerably from that of rapidly growing intracranial tumors certainly

Fig. 1.—Perithelial hypertrophy occurring around the vessels of a glioma: *a*, hematoxylin and eosin,  $\times 80$ ; *b*, Perdrau's method,  $\times 80$ . Note that each cell is surrounded by reticulin.

of neuro-ectodermal origin. I have never found any evidence to support the possibility of sarcomas arising from the microglia of del Río-Hortega. The terminology used will be for the most part purely descriptive, depending on the gross microscopic picture and on the histofunctional differentiation of the neoplastic cells.

#### PERITHELIOMA

It is well known that the cerebral blood vessels are surrounded by a sheath of cells of leptomeningeal origin. The structure and relationships of this perithelium have recently been made the subject of an

extensive review by Schaltenbrand and Bailey. An overgrowth of this perithelium is occasionally seen in gliomas. Figure 1 portrays an excellent example.

Tumors of this perithelium occur which demonstrate in the most striking way the common origin of the perithelial and of the leptomeningeal cells over the surface of the brain. The first of these tumors was described by Eberth in 1870. He showed by the examination of teased preparations that the surface of the arachnoidal strands and the vessels of the cortex, even the capillaries to a depth of 1 cm., were covered by a layer of large rounded cells, rarely 2 or 3 cells deep (fig. 2 *a*). Occasionally, among them were seen giant cells.

Fig. 2.—*a*, copied after Eberth. Note the resemblance to the tumor in figure 3, *b*. *b*, a similar tumor of Haeger, showing the same swollen meningeal cells in the subarachnoid space.

A similar tumor from this clinic was recently described by Connor and Cushing, which showed clearly that the neoplastic cells continued from the perivascular perithelium into the pia mater over the surface; furthermore, that the perithelial tumor had developed in situ and was not an invasion from the subarachnoid space of the perivascular space of Virchow-Robin (fig. 3). They called attention to comparable cases published by Marcus and by Cassirer and Levy. To these may be added others by Haeger (fig. 2 *b*), by Janssen, by Berblinger and by Schaede, possibly also the second case of Manganotti.

The tumor described by Berblinger needs further notice for the reason that the perivascular cells were filled with granules of melanin.

It is known that there are melanin-bearing cells to be found normally in the leptomeninx, even in its perivascular extensions (Virchow, Obersteiner), but the origin of these cells is disputed. Nor is there any generally accepted opinion as to the origin of the melanotic cells of the skin, the so-called dendritic cells. Ribbert and Hortege maintained that they were mesodermal, but the ectodermal theory seems to be gaining ground and has been logically developed by Masson.

Fig. 3.—Diffuse tumor of the perithelium (case of Connor and Cushing): *a*, Bielschowsky-Plein,  $\times 80$ ; *b*, Perdrau's method,  $\times 850$ . Note that the tumor cells attached to the wall of the capillary are surrounded by reticulin.

It was pointed out by Bruno Bloch that the melanin-forming cells contained an oxydase which he called dopa-oxydase by a contraction of the name of the reagent used for its demonstration. This oxydase he showed to reside in the basal cells of the epidermis. Since the dendritic cells contain also the oxydase, Masson supposed that they are ectodermal and that the basal cells of the epidermis follow a double evolution, malpighian and dendritic, each resulting in cells which are

melanoblastic since they contain the essential oxydase. He has recently abandoned this theory in favor of a neuro-ectodermal origin for the dendritic cells. At any rate, in order for melanin to form it is necessary that the oxydizable substance, chromogen, be brought to the cells by way of the blood stream and mesodermal cells of the corium.

Whether melanin is formed by other than ectodermal cells is at present a subject of controversy (Bloch). Concerning the pigmented cells of the choroidal coat of the eye, Dawson said "Embryological data entirely support the view of the origin of the pigmented cells of the choroid and of the stroma of the iris by migration of cells from the pigmented layer of the retina and the pars iridis retinae. The pigmented cells of the choroid, therefore, are not mesoblastic but neuro-epithelial in origin. . . ." Even the mongolian spots and blue nevi studied by Sato and by el Bahrawy cannot be certainly considered to be mesodermal in view of Masson's theory of the neuro-ectodermal origin of all nevi. Walthard has pointed out that the pigment of intestinal melanosis does not give a dopa reaction.

The presence of melanin in the cells of the leptomeninx pleads, therefore, in favor of an ectodermal origin of these cells, but does not prove such a derivation, for a positive dopa reaction has not been obtained from them. If the leptomeninx is of ectodermal origin, the presence in it of melanoblasts is easily understood; they result from a differentiation out of the matrix of the leptomeninx such as that of the dendritic cells in the basal layers of the epidermis. On this basis it is easy to understand an abnormally extensive pigmentation of the leptomeninx (Virchow) as an exaggeration of this evolution, and also the association of abnormally extensive pigmentation of the leptomeninges and skin (e. g., in Berblinger's case) as a generalized over-development of melanoblasts. By this hypothesis it is also easy to understand why the pigmented tumors of the leptomeninx differ in no way in structure from those which are not pigmented, as will be clearly evident from the following descriptions.

The fact that in these perithelial tumors the neoplastic cells continue out into the pia mater leads to a discussion of that ill understood condition usually described as "sarcomatosis of the meninges." I am not speaking of those cases of diffuse infiltration of the meninges by metastasis from tumor elsewhere in the body, but rather of those tumors primary in the intracranial and intraspinal cavities of which there are two types: (1) those primary in the meninges and (2) secondary infiltration of the meninges from tumor of the central nervous system.

Surely it is not a coincidence that all recorded cases of perithelial tumors which are clearly leptomeningeal, and almost invariably extend into the meninges over the surface to form a "sarcomatosis" or

"endotheliomatosis," occurred in adults (Eberth, aged 47; Marcus, 48; Haeger, 48; Janssen, 30; Cassirer and Levy, 40; Connor and Cushing, 63; Schaepe, 22). On the other hand, Rach has already pointed out that the diffuse infiltration of the meninges secondary to a primary tumor of the nervous tissue almost invariably occurs in children. Bailey and Cushing showed further that the tumor of the nervous tissue in these cases was a peculiar type of glioma which they called medulloblastoma. Thus even apart from the variation in histologic structure of these tumors there is evidence, from the age of onset, of a radical difference existing among the diffuse tumors which are primarily intracranial.

Perhaps an insight into the microscopic structure of those diffuse tumors believed to be primarily of leptomeningeal origin can best be obtained by beginning with a study of those which arise from the intracerebral perivascular extensions of the leptomeninges. The case of Schaepe makes a good starting point. In certain areas the vessels were not surrounded simply by one layer of swollen cells but rather by cuffs of cells, half a dozen or more cell layers in thickness to form a typical gross appearance often called a *perithelioma*. The same arrangement was seen in the tumor in the following case.

*CASE 1.—Midcerebellar syndrome. Suboccipital exploration. Death from hyperthermia. Necropsy. Diffuse tumor of the pia-arachnoid.*

*History.*—B. R., aged 3, referred by Dr. Henry Utter of Providence, R. I., was admitted to the hospital on Oct. 13, 1927, complaining of headache, vomiting and difficulty in walking.

The child had always been delicate but had no definite complaint until Aug. 1, 1927, when he had a cervical adenopathy with fever. On September 15, his tonsils were removed. On September 22, he complained that his head felt "tired," and he vomited. From that time on he vomited several times a day, suddenly, without warning, and without seeming to be ill. He soon complained of pain in the back of the neck, and about October 1, it was noticed that he walked unsteadily. Lately he was drowsy, breathed irregularly and squinted.

On admission, he was irritable, uncooperative, emaciated, yawning and drowsy. The head seemed to be increased in size, but no cracked pot sound could be elicited on percussion. There was bilateral choking of the optic disks (from 3 to 4 diopters elevation), left abducens weakness, hypotonicity and ataxia of cerebellar type of all the extremities, especially of the lower extremities, and staggering gait. Nystagmus was absent.

The clinical diagnosis was central cerebellar tumor, possibly in the fourth ventricle.

*Operation.*—On Oct. 15, 1927, at 10:25 a. m., a suboccipital exploration was made by Dr. Cushing. Puncture of the lateral ventricles obtained only a few drops of fluid from each, showing that there was no internal hydrocephalus. Nevertheless the clinical picture was so definite that the operation was continued. No evidence of tumor was found.

*Course of Illness.*—A hyperthermia developed immediately, which could be only temporarily reduced by energetic hydrotherapy. He became cyanotic and had

almost continuous convulsive movements of the left side of the body. This side of the body was also distinctly warmer than the right. He failed gradually, and died on October 16 at 5:05 a. m.

*Necropsy.*—Permission to examine the head only was obtained. The brain was perfused with 10 per cent formalin immediately after death, the solution being introduced through lumbar-puncture needles into the lateral ventricles and drained from the posterior cistern in the same manner; it was then carefully removed and immersed in 10 per cent formalin for further fixation. It was evident, on superficial examination, that there was a cloudy thickening of the leptomeninges practically all over the brain, looking something like that seen in tuberculous meningitis, but not so marked. Medial sagittal section of the brain and parasagittal sections through each hemisphere showed no evidence of tumor. Since

Fig. 4 (case 1).—Meningeal tumor to the right; sheath of cells around vessel deep in the substance of the cerebellum; methylene blue-eosin,  $\times 100$ .

microscopic examination, however, revealed a diffuse tumor in the meninges, blocks were taken from the frontal, cingular, central, insular, calcarine, parietal and supramarginal regions of the cortex of each hemisphere, also from the medulla, roof of the fourth ventricle, pineal body, roof of third ventricle, tuber cinereum, pons, hippocampus, basal ganglions and cerebellum. These blocks were embedded in paraffin and sections were stained with methylene blue-eosin, hematoxylin and eosin, phosphotungstic acid hematoxylin, resorcin-fuchsin, mucicarmine, and by the methods of Bielschowsky, Bielschowsky-Plein, Loyez, van Gieson and Perdrau. They all showed the same picture. Everywhere the leptomeninx was transformed into a tumor (fig. 4). It cannot be said that the pia-arachnoid was infiltrated by tumor for there was no trace of normal pia-arachnoid cells. With the exception of the endothelial lining and occasionally a few smooth muscle cells in the walls

of the larger vascular channels, this tumor was composed throughout of large rounded or polygonal cells, lying in a compact mass with no intercellular bridges, and apparently not adherent to each other. These cells had abundant cytoplasm. The nuclei tended to be vesicular or of irregular shape, with a heavy nuclear membrane often crenelated, with very little chromatin, and one or two heavy nucleoli. Mitotic figures were easily found.

An abundant network of fine reticular fibrils was present among the tumor cells, often forming concentric rings about the vessels, many of which had no other lining than the tumor cells (fig. 5). The network was evidently formed by the neoplastic cells since no other cells could be seen along the fibrils. No collagen, elastin nor fibroglia were found except in the walls of the larger vessels.

The neoplastic cells followed along the vessels into the brain, even into the depths of the white matter, and formed cuffs (fig. 6) around them varying from

Fig. 5 (case 1).—Section stained by Perdrau's method,  $\times 600$ ; vascular sinus in the meningial tumor formed and lined by neoplastic cells.

one to several cells in thickness, but it was important to note that there was no sheath of reticulin or collagen between these cells and the nervous tissue (fig. 7), neither was there any such layer between the pia mater and the nervous tissue over the surface (fig. 8).

In the leptomeninx, extensive degenerative changes were going on in many places, leaving cuffs of viable cells only around the vessels.

*Comment.*—Apparently this tumor is entirely similar to the one described by Nonne, although the illustrations he gives are at such low magnification that positive identification is impossible.

Unfortunately, in case 1 the spinal cord could not be removed, and a complete necropsy could not be done, so that absolute proof that the

tumor was primary in the meninges cannot be given. There are, nevertheless, dependable arguments that such was the case.

Metastatic tumors grow in the brain in discrete nodules and do not follow the perivascular spaces to any great extent. If the metastasis occurs in the subarachnoid space and from there invades the perivascular tissues there is always a distinct layer of collagen between the infiltrate and the glia; the same is true of the subarachnoid space. Such a layer was entirely absent in the present case, showing that the tumor arose as a direct transformation of the leptomeninx.

Fig 6 (case 1) —*a*, section stained with methylene blue-eosin,  $\times 300$ , subcortical vessel surrounded by collar of neoplastic cells as in case of Schaefer; *b*, Perdrau's method,  $\times 300$ , similar vessel, showing reticulum and absence of pia-arachnoid sheath.

That the tumor is not a glioma is abundantly proved by the type of cell and by the formation of reticulum by the neoplastic cells.

It is interesting from a theoretical point of view to note that although the perivascular tissue was directly transformed into tumor there was no evidence of a Virchow-Robin space around the deeper vessels where such a transformation had not taken place, as one might expect were there normally a current of fluid along the spaces of this tissue toward

Fig 7 (case 1)—Cross-sections of small cortical vessels *a*, methylene blue-eosin,  $\times 850$ , *b*, Perdrau's method,  $\times 850$  Neoplastic transformation of the perithelium and the absence of normal pia-arachnoid cells

Fig. 8 (case 1).—Small vessels penetrating the cerebral cortex: *a*, methylene blue-cosin,  $\times 600$ ; *b*, Perdrau's method,  $\times 600$ . Note the serrated border of the neoplastic perithelium, and the absence of fibrous pia-arachnoid sheath.

the subarachnoid space (see Schaltenbrand and Bailey). Nor were the perivascular and perineuronal shrinkage spaces of His and of Obersteiner abnormally dilated. The nervous parenchyma was microscopically normal with the exception of an acute swelling of the oligodendroglia.

The tumor was, therefore, in all probability a primary sarcoma of the leptomeninx.

In certain areas of this tumor over the surface of the cortex the intervacular degeneration had begun to result in a pseudoperithelial arrangement. I agree with Roussy and Ameuille in their contention that the term "perithelioma" as used in the literature means only a gross microscopic picture in which the blood vessels are surrounded by cuffs of neoplastic cells. It signifies also the appearance which arises in many tumors by degeneration of the neoplastic cells between the vessels, except perhaps in the case of the coccygeal body. Yet there are undoubtedly in the central nervous system tumors properly called peritheliomas, that is to say, tumors which grow from the perivascular leptomeningeal sheath. I believe that I have been able to assemble sufficient examples to follow their evolution.

The first stage is represented by tumors such as those of Eberth, Marcus, Connor and Cushing, etc., before mentioned. The second stage may be followed in the tumor of Schaede and in case 1 just described where, as mentioned in a previous paragraph, in certain areas the cortical vessels are surrounded by thick cuffs of leptomeningeal cells. The same picture was seen in Berblinger's case and may also be seen in tumors of the sheath of the optic nerves. In each of these cases the sleeves of tumor, however, are still separated by normal cerebral tissue. The third stage of development is well demonstrated by a tumor which Dr. Charles Bagley allowed me to examine, and it is to be hoped that he will describe it more fully soon.

One could clearly see in Bagley's tumor how it advanced perivascularly, leaving islands of sclerotic brain tissue between the advancing fingers (fig. 9a), these islands being finally destroyed as the tumor closed in on them. But a simultaneous evolution was going on which resulted again in a perithelial appearance due to intervacular necrosis (fig. 9b), and I am convinced that most of the peritheliomas of the brain which have been described in the literature are of this type.

It is undoubtedly true that intervacular necrosis may occur in gliomas, especially in the spongioblastoma multiforme and astroblastoma, but here the necrosis never results in such compact sleeves of perithelial cells. In the case of the small cell medulloblastoma, which might be most easily confused with the perithelial leptomeningeal tumors, such intervacular degeneration rarely occurs, and the cellular type is easily distinguished.

Fig. 9 (case of Dr. Charles Bagley).—Sections stained with hematoxylin and eosin,  $\times 80$ . In *a*, note the sclerosed cerebral tissue between the extensions of the tumor, also the necrosis at *X*. *b*, typical picture of perithelioma resulting from intervascular necrosis.

Even in the case of a spongioblastoma multiforme which had herniated through a decompression to form a huge extracranial extension, and in which there was an intimate mixture of glial and mesodermal tissue, I have found it always possible to distinguish the two tissues. The cytoplasm of connective tissue cells is denser and stains more heavily with eosin, while that of the glial cells is delicate and less heavily stained (fig. 10). The nuclei of the glial cells are oval with delicate regular nuclear membranes and scattered grains of chromatin. The nuclei of the connective tissue cells, on the other hand, are much

Fig. 10—Two photographs from a spongioblastoma multiforme which had herniated through a decompression to form a huge extracranial tumor. Degenerative and reparative processes led to an intimate mixture of glial and fibroblastic tissue; yet even with an ordinary nuclear stain it was possible to distinguish the two tissues. Note that the glial nuclei are smaller, more regularly oval, with abundant chromatinic granules. The nuclei of the connective tissue cells are larger, more vesicular, and of more irregular shape. With special staining methods the distinction is easy. *a*, methylene blue-eosin,  $\times 850$ ; connective tissue right, glia left. *b*, hematoxylin and eosin,  $\times 600$ ; connective tissue above, glia below.

more irregularly shaped; the nuclear membrane is heavier and often crenelated, and the chromatin is dustlike and peripherally situated so that the nuclei have a vesicular appearance and the nucleoli are very prominent. I have never been able to find any evidence in favor of the conjunctivoneuroglial metaplasia described by Bertrand and Medakovitch.

The first tumor unquestionably of perithelial type in the literature, as far as I am aware, was recorded by Cornil. It seems to me certain that such tumors as those described by Coste and Levy, Besold, Wätzold, etc., are also of leptomeningeal origin even though the perithelial arrangement is due to intervacular necrosis, but the photographs are at such a low magnification and the microscopic descriptions so rudimentary as to make positive identification impossible. They all agree, however, in being formed of small rounded cells with nuclei of connective tissue type and practically no intercellular substances.

I would not go so far as to say that all tumors of this type arise from the perithelial (perivascular) leptomeninx. The tumor in the following case, although the cellular type is identical with that in the preceding cases, seems to have arisen from the leptomeninges over the surface of the brain and to have pushed the cerebrum aside without invading it. This tumor, by reproducing the cellular structure of the tumors of perithelial origin, furnishes another proof of the identity of the leptomeninges and the perivascular sheath.

*CASE 2.—Leptomeningeal tumor of perithelial type. Right subtemporal decompression. Right osteoplastic exploration with fatality. Necropsy.*

*History.*—On April 16, 1921, Pauline T., aged 12, referred by Dr. C. Bartlett, of Norfolk Downs, Mass., was admitted to the hospital, complaining of pain over the right frontal region and loss of vision.

She was one of twins, born at 7 months, but had always been well except for an attack of jaundice at the age of 7.

In October, 1920, it was observed by her teacher that her vision was defective. She was taken to an ophthalmologist who recommended glasses which gave her no relief. In December, she began to have nausea and vomiting. In January, 1921, it was noticed that she dragged her left leg. Later she became bedridden from weakness, was very drowsy, complained of pain in the right frontal region, and her vision failed rapidly.

On admission, she was found to be emaciated, and dull mentally. Her head was enlarged, the extracranial veins enlarged, the temporal regions very prominent, and a cracked pot sound was produced by percussing the head. The optic disks were elevated from 5 to 6 diopters, with hemorrhages and formation of new tissue, so that she was almost completely blind. There was a left hemiparesis and hemihypesthesia.

On April 20, 1921, a right subtemporal decompression was done by Dr. Horrax disclosing a tense brain but no tumor.

*Course of Illness.*—The optic disks subsided to 3 diopters and the patient became more alert. The decompressed area bled and was very tense.

On May 5, a right osteoplastic exploration was made by Dr. Horrax with the flap placed anteriorly. In the anterior margin of the incision the bone was found to be thickened and very vascular. The dura under this region was roughened and very vascular also. When it was reflected, the margin of a reddish, apparently encapsulated, tumor was exposed. No attempt was made to enucleate the tumor because of the patient's feeble condition. A transfusion was made immediately, but death soon occurred.

*Pathologic Examination.*—Necropsy was confined to the head. The brain was removed twelve hours post mortem, and was fixed by immersion in 10 per cent formalin. On the inner surface of the right frontal bone was found a crater-like thickening corresponding to the location of the tumor. The latter was definitely encapsulated, attached to the under surface of the dura mater, dark red and soft. It measured 15.5 by 18.8 cm. in diameter.

*Microscopic Description.*—Portions of the tumor, which had been fixed in formalin, were embedded in paraffin. Sections were stained with hematoxylin and eosin, by van Gieson's, Verhoeff's and Perdrau's methods and with phosphotungstic acid hematoxylin.

Fig. 11 (case 2).—*a*, section stained by Perdrau's method,  $\times 80$ ; *b*, hematoxylin and eosin,  $\times 80$ . Perithelial arrangement due to colloidal intervascular degeneration.

The microscopic picture was that of a typical degenerative "perithelioma" (fig. 11). The numerous blood vessels were surrounded by compact sleeves of tumor cells. This perivascular arrangement was produced by degeneration of those cells farthest away from the vessels.

The neoplastic cells were small and round, with spherical nuclei and scanty cytoplasm. The nuclei had heavy nuclear membranes and fine granules of chromatin. Mitotic figures were rarely seen (fig. 12).

The cells immediately surrounding the vascular sinuses were different from those farther away. They had abundant cytoplasm, which stained well with eosin, and their nuclei had a tendency to be elongated, with an angular or crenelated contour. These cells formed fibrils of collagen and reticulin. No elastin was present.

In many areas it was possible, however, to see that there was an insensible transition between the two types of cells (fig. 13 a) which seemed therefore to be a differentiation from a common source. The reticulin often extended diffusely among the rounded neoplastic cells (fig. 13 b).

The tumor in Hashimoto Schozo's second case seems to have been very similar to the tumor just described (fig. 14).

Fig. 12 (case 2).—Section stained with hematoxylin and eosin,  $\times 300$ . The bodies of the cells are round and their nuclei those of connective tissue with heavy cellular membrane, often crenelated, dustlike chromatin and heavy nucleolus.

#### PERITHELIAL SARCOMA

The foregoing tumors have been rather slowly growing, did not break through the pia glia membrane and perhaps do not merit the name of sarcoma, but they constitute a somewhat necessary introduction to the other perithelial tumors of much more rapid evolution. In the following case the tumor is a perivascular sarcoma, doubtless

developing from a single focus in the leptomeningeal sheath, as it was a single large mass deep in the substance of the cerebral hemisphere. It occurred among about 100 verified tumors in Dr. Cushing's Johns Hopkins Hospital series prior to 1912.

CASE 3.—*Perivascular sarcoma of the right temporal region Osteoplastic extirpation. Fatality. Necropsy.*

*History.*—On Jan 9, 1911, George P., aged 45, a business man, was admitted to the hospital, complaining of headache, convulsions and difficulty in speaking.

He had always been well until about a year before admission, when he became somewhat irritable, was unable to concentrate on his work and had some family difficulties.

Fig. 13 (case 2) —*a*, section stained with hematoxylin and eosin,  $\times 700$ ; transition from the loose neoplastic cells to those of the vessel wall. *b*, Perdrau's method,  $\times 300$ ; reticulin fibrils extend out among the neoplastic cells.

In July, 1910, he was found by his physician to be slightly confused and somewhat aphasic. The fundi at this time were slightly hazy. By the end of July he had an almost complete motor aphasia and was unable to say anything except "By Jove." The Wassermann reaction was negative at this time, but he was put on antisyphilitic treatments and the aphasia disappeared. On October 29, he complained of seeing double. At this time, the fundus was normal but there was a weakness of the left external rectus muscle. On November 26, he was unsteady on his feet for the first time. There was also some drooping of the left side of the mouth.

On December 15, he again became confused and aphasic and had a series of convulsions followed by stupor and left-sided hemiparesis. On December 17, he

had a series of focal convulsions involving the right side of the face and throat, and sometimes the arm, without loss of consciousness. After that he was sometimes worse, sometimes better, with occasional convulsive attacks, complaining of headaches, suboccipital in location, nausea and vomiting.

*Examination.*—On admission to the hospital, there was found a lower facial weakness on the left side; weakness of left arm and leg; abdominal reflex was absent on the left side; Babinski sign on the left; exaggeration of the tendon reflexes on the left side; bilateral choked disks of from 3 to 4 diopters. There was tenderness on pressure over the right temporal region and the right suboccipital region. There were some nystagmoid movements on looking to the extreme right. The right eye was slightly more prominent than the left. There was a left hemihypesthesia. The tongue protruded slightly to the left. No evidence of

Fig. 14.—Copied from Schozo. Tumor resembling in structure that in case 2.

aphasia was noted, but he was a little slow in his responses and forgetful. There was a definite disturbance of the muscle sense on the left side.

*Course of Illness.*—On Jan. 13, 1912, a right osteoplastic exploration was made by Dr. Cushing. On opening the dura, the brain was found to be tense and the cortex bulged markedly. There was some thickening and vascular changes in the meninges, but the cortex showed no abnormalities. The patient recovered promptly but continued to be a little drowsy and the left arm and hand became weaker. By January 24, a puncture was made of the right ventricle. No fluid was obtained at a depth of 6 cm. A left subtemporal decompression was then made. The cortex appeared normal, but under considerable tension. The patient did fairly well after this second intervention, being at times bright, but at other times stuporous. By February 2, he was again stuporous and had Cheyne-Stokes respiration. On February 2, the original bone flap was reelevated disclosing a tense bulging brain. An incision about 8 cm. in length was made parallel to the *postcentral* convolution down to a roundish tumor (fig. 15), about the size of a hen's egg, which was

gradually separated from the brain tissue and lifted out. The wound of the brain was allowed to fall together. The bone flap was removed and the scalp sutured.

After this intervention the patient remained in a comatose condition, and had persistent hiccupping and twitching of the right nasolabial region. His temperature continued high, around 101 to 102 F. He became gradually weak, and on February 9, died.

*Necropsy.*—A complete necropsy was performed and there was found only a bronchopneumonia and an operative wound of the right cerebral hemisphere. No evidence was found of an extracerebral tumor of any kind. A section of the brain was made on a horizontal plane just above the corpus callosum. The central part of the right hemisphere was occupied by an irregular mass of blood clot and traumatized tissue. The ventricles were dilated and the corpus callosum was displaced downward on the right side.

Fig. 15 (case 3).—Neoplastic tissue removed at operation

*Microscopic Examination.*—There was available for examination a portion of the tumor, fixed in formalin, and the brain from which the tumor was removed. Sections of the tumor were stained with hematoxylin-eosin, phosphotungstic acid-hematoxylin and by Perdrau's method.

The tumor was composed of a mass of small rounded cells with scanty cytoplasm. Numerous blood vessels were present, and the neoplastic tissue had often degenerated between them so that the cells formed thick sleeves around the vessels (fig. 16). Here they lay closely together without architectural arrangement. The nuclei had fine granules of chromatin, evenly distributed, but their surfaces were often irregular and angular. Mitotic figures were numerous. The only fibrillary material found was reticulin, often lying in a haphazard way between the cells, but more often forming concentric circles around the vessels (fig. 17). The neoplastic cells within and without these circles were identical. The reticulin must have been formed by the neoplastic cells, since no cells distinct from them could be found nearby.

Fig. 16 (case 3).—Rounded cells and vesicular nuclei and numerous mitotic figures are seen. Note that the reticulin is laid down by the neoplastic cells; hematoxylin-eosin,  $\times 300$ .

Fig. 17 (case 5).—General architecture of tumor: *a*, hematoxylin-eosin,  $\times 80$ ; *b*, Perdrau's method,  $\times 80$ . Note concentric circles of reticulin around vessels.

Dr. F. B. Mallory, who examined sections of the tumor in 1911, made the following note: "I have ringed a vessel in one section which shows the tumor to have grown between the lining endothelium and the vessel-wall. This is a characteristic more commonly seen in tumors belonging to the lympho-sarcoma or malignant lymphoma. If you examine the section under oil you will find numerous endothelial leucocytes with remains of tumor cells in them. This is another common occurrence in tumors of the lymphocyte series, but proves nothing positively."

Sections of the brain in the region of the operative wound showed, in addition to gliosis and hemorrhages, the advance of the tumor. It progressed occasionally along the perivascular spaces of Virchow-Robin, more often diffusely, but usually along the zone of least resistance around the vessels which is known as the space of His.

Fig. 18.—Cerebral metastasis from melanotic sarcoma showing concentric rings of reticulin: *a*, hematoxylin-eosin,  $\times 150$ ; *b*, Perdrat's method,  $\times 150$ .

The tumor must have been a sarcoma arising most probably from the leptomeningeal perivascular sheaths.

The same distribution of the reticulum is often seen in metastatic sarcomas (fig. 18) but never in gliomas. It was shown excellently by the tumor in the following case in which a necropsy was not obtained. The lesion cannot, therefore, be regarded as certainly being a primary tumor of the brain. The nature of the neoplastic cells and the arrangement of the reticulum, however, make it certain that the tumor is a sarcoma and not a glioma, and the fact that the tumor was not sharply circumscribed makes one feel that it may have been primarily cerebral.

CASE 4.—*Perivascular sarcoma of the left temporal region. Osteoplastic exploration. Death two months later. No necropsy.*

*History.*—Aaron G., aged 65, referred by Dr. Frank F. Sandler, of Revere, Mass., was admitted to the hospital on Jan. 3, 1924, complaining of weakness and ringing in the ears.

He had been melancholic for a couple of years, because he felt his strength and memory were failing. He complained of buzzing in his ears occasionally, but was not actually ill until the early part of November, 1923, when he began to have severe frontal headache accompanied by vomiting. Soon after this time, his vision failed slowly. He became very dull and emotionally unstable.

On admission, he was dull and emotional and had definite anomia and agraphia. There were bilateral choked disks with from 3 to 4 diopters elevation. In

Fig. 19 (case 4).—*a*, section stained with methylene blue-eosin,  $\times 100$ ; perithelial arrangement resulting from intervascular necrosis. *b*, Perdrau's method,  $\times 100$ ; concentric circles of reticulin around the vessels.

addition, there was paresis of the left abducens nerve, slight ptosis of the left upper eyelid and a right hemihypesthesia and exaggeration of the right knee reflexes and ankle jerks.

On Jan. 15, 1924, in the course of a left osteoplastic operation, Dr. Horrax found a small area about 1 cm. in diameter in the superior temporal gyrus. It was yellowish and shaded off into the surrounding brain tissue without any sharp line of demarcation. The temporal region was bulging and the sylvian vessels displaced upward. Puncture of the temporal lobe disclosed no cyst. A portion of the superficial tumor was removed for microscopic study.

*Course of Illness.*—The patient was discharged on Jan. 25, 1924, in about the same condition as he was on admission. One roentgen treatment was given, but he failed rapidly and died on March 13. Unfortunately, necropsy was not obtained.

*Microscopic Description.*—The material obtained at operation was fixed in Zenker's fluid and embedded in paraffin. Sections were stained with methylene blue-eosin, phosphotungstic acid hematoxylin, aniline blue-orange G, and by Perdrau's method.

The tumor was composed of a mass of rounded cells of varying sizes, closely packed together, loosely arranged and degenerating between the vessels (fig. 19). These cells did not seem to adhere to each other like epithelial cells. The nuclei were surrounded by a narrow ring of cytoplasm which stained rather heavily with methylene blue. The nuclei tended to be spherical but were not of regular shape; many were angular. The nuclear membrane was heavy, often crenelated, the granules of chromatin were fine and the nucleoli prominent. Mitotic figures were numerous (fig. 20 a). Occasionally, multinucleated cells were seen

Fig 20 (case 4).—a, section stained with methylene blue-eosin,  $\times 300$ ; rounded cell bodies and vesicular nuclei are clearly shown; mitotic figure in lower part of photograph b, Perdrau's method,  $\times 300$ , concentric arrangement of the reticulin, the outer layer being fragmented.

The only connective tissue fibrils to be found were of reticulin, which formed concentric rings around the thin-walled vascular sinuses (figs. 19 b and 20 b). The cells within and without these rings were identical. The reticulin must have been formed by the neoplastic cells for other cells were not seen along its strands. The tumor was not sharply circumscribed as is usual with metastatic tumors. It was a round cell sarcoma, probably primarily intracranial.

So far as one can judge from the description given, a very similar tumor has recently been described by Zagni (case 1). He concluded from his study that the tumor was best described as a large round cell sarcoma.

Another remarkable example of what is doubtless a perithelial sarcoma has recently been reported from this clinic by Fried. This unusual growth, in which mitotic figures were very numerous, seems to have developed simultaneously along the vessels in many regions of the brain, which is perhaps not astonishing when one remembers that in the case of the more slowly growing perithelial tumors already mentioned, widely separated and entirely independent foci were found in several instances.

Tumors of the same type may be melanotic, as was well seen in a case which Dr. K. G. McKenzie permitted me to study (fig. 21 *a*). Since a complete necropsy was not done in his case it is again impossible

Fig 21 (kindness of Dr. K. G. McKenzie)—*a*, section from a melanotic sarcoma of the pia mater. Note the concentric rings of reticulum around the vessels. Perdrau's method, 80  $\times$ . *b*, copied after Boit, from a melanotic meningeal tumor. Note the concentric arrangement of the cells and the character of the nuclei.

to be certain that the tumor was primarily intracranial, but that entirely similar tumors may arise primarily in the central nervous system is proved by the observations of Minelli, Thorel, Stoerck, Virchow, Hirschberg, Sternberg (microscopic description given later by Schopper), Boit, Omodei-Zorini, Feller and others. Although the reticulum is not figured by Minelli, the same circular arrangement of the cells around the vessels is clearly portrayed in the case of other melanotic tumors of the meninges, for example, that of Boit (fig. 21 *b*), and is also mentioned by Thorel.

## FIBROBLASTOMA

It will be noted that none of the tumors just described resembled any more closely the ordinary fibroblastoma of the extracranial connective tissue than do the meningiomas or acoustic neurinomas. In fact, the only typical fibroblastoma proved by necropsy to be primary in the brain with which I am familiar is the following one of Dr. F. B. Mallory which he has allowed me to report here.<sup>1</sup>

*CASE 5.—Fibroblastoma of the right temporal lobe. Death without operation. Necropsy.*

*History.*—Mary T., aged 42, was admitted to the Boston City Hospital, on Dec. 26, 1909, in a semicomatose condition.

Three months before admission, on arising from the breakfast table, she fell to the floor unconscious and remained so for three or four hours. After that time she had severe frontal headaches. She vomited two or three times, until within two weeks of entrance. At this time some teeth were pulled, and on going home she noticed some twitching of the left leg which continued for the next two weeks.

*Examination.*—On admission, she was conscious but very stupid. The pupils were equal and did not react to light. There was a dorsal toe response to plantar stimulation on the right side. No other pathologic conditions were noted.

On December 27, she became more stupid, and died before any diagnosis was made.

*Necropsy.*—Necropsy was performed one and two-third hours post mortem by Drs. Backan and Hunter. Examination of the body revealed a healed tuberculous lesion of the apex of the left lung and acute suppurative otitis media and mastoiditis on the right side. The brain was removed without previous fixation. Dr. Hunter's description reads in part as follows:

"On removal of the dura the convolutions appear flattened; the brain is exceedingly dry, and sticky to handle. The blood-vessels are small and do not contain much blood. The temporal lobe on the right side is larger than on the left; it is adherent in the anterior and inferior portion to the dura. These adhesions are moderately firm and extend backward to about the middle of the inferior temporal convolution. The dura over the petrous portion of the temporal bone is removed with this tumor mass; otherwise dura is not remarkable. The lateral sinuses of the brain are negative.

"The brain is taken out and coronal sections of the frontal lobes reveal nothing remarkable until the right temporal convolutions are sectioned, where a tumor is encountered, which measures 5.5 cm. in its lateral diameter; 4.8 cm. in its vertical diameter and approximately 3.4 cm. in its antero-posterior diameter (fig. 22). Section of this tumor shows the outer portion to be semi-opaque, somewhat cartilaginous in character, parts being fairly firm with irregularly scattered streaks of red markings, apparently blood-vessels. The central portion is opaque, soft, friable and of a greyish-yellow color. The capsule on the outside, where it is adherent to the dura, is smooth and well defined; on the inner portion it is fairly

---

1. Typical fibroblastic tissue may often be seen in degenerating gliomas and, when a small fragment is removed at operation, may readily lead to an erroneous diagnosis of fibroblastoma. This has happened to me in one recent case in which the tumor proved later to be a glioma. It is a source of error to be carefully avoided in the study of surgical specimens.

# BAILEY—SARCOMATOUS TUMORS

well defined by a greyish-yellow margin, with internal to this the aforementioned semitransparent cartilaginous portion. Inferiorly the tumor is bounded by the dura; superiorly by the white and grey matter over the Rolandic area; internally by the cortical tissue, partially occupying the island of Reil and adjacent to the claustrum. The ventricles are apparently of normal size. The right lateral ventricle appears somewhat compressed toward the median line, the basal nuclei apparently pushing upward and inward into the lateral ventricle; thus, the outer margin of the right lateral ventricle appears to be in about the median line. The remaining portion of the brain has not as yet been sectioned, being preserved as a gross specimen.

Fig 22 (case 5, kindness of Dr. F. B. Mallory) —Sketch of coronal section of brain made at necropsy a, solid neoplastic tissue; b, necrotic center

"Sections of the brain show a fibrosarcoma in the area mentioned, the central portion showing marked necrosis."

*Microscopic Description* —Blocks of tissue which had been fixed in Zenker's fluid and embedded in paraffin were given to me by Dr. Mallory. Sections were stained with hematoxylin and eosin, van Gieson, phosphotungstic acid hematoxylin, neutral ethyl violet-orange G, by Perdrau's and by Verhoeff's methods.

The tumor was seen to be composed of spindle cells (fig. 23) with elongated nuclei having a heavy nuclear membrane, finely granular chromatin and prominent nucleoli. Mitotic figures were numerous. Between the cells were numerous reticulin (fig. 24 a) and collagenic fibrils, but no elastin. Many fibroglial fibrils were easily demonstrated (fig 24 b).

The microscopic structure was that of a typical fibroblastoma.

Fig. 23 (case 5).—Section stained with phosphotungstic acid hematoxylin,  $\times 150$ ; spindle cells with elongated nuclei characteristic of fibroblastoma.

Fig. 24 (case 5).—*a*, section stained by Perdrau's method,  $\times 150$ ; numerous reticulin and collagenic fibers. *b*, neutral ethyl violet-orange G,  $\times 850$ ; fibroglial fibrils.

There is no example in my collection of a typical fibroblastoma of the brain of this type, nor have I found any examples described in the literature unless Zagni's case 2 may be such a lesion rather than a spongioblastoma multiforme. If, as Dr. Mallory believes possible, the tumor arose from the scar tissue of a healed abscess, the uniqueness of this neoplasm may be understood. I should like, nevertheless, to include the following two cases in this study, although a complete necropsy was not obtained in either, because of the typical structure of the tumors,

Fig. 25.—Cross-section through brain and tumor from case 6. The tumor is evidently sharply circumscribed from the cerebral tissue.

approaching that of the ordinary spindle cell sarcoma of the peripheral tissues. There is no reason to suppose that they were metastatic except for the rarity of such tumors in the intracranial cavity.

*CASE 6.*—Meningioma of fibrosarcomatous type in the right temporal region. Left subtemporal decompression. Death three months later. Necropsy.

*History.*—Martha C., aged 27, referred by Dr. E. L. Sawyer of Roslindale, Mass., was admitted to the hospital on Jan. 3, 1916, complaining of headache and failing vision.

She had been well until July, 1915, when she began to have occasional headaches. Her eyesight had failed steadily since this time, and several times lately she had the impression that there was a red wall on her left side. Vomiting occurred infrequently.

She was somewhat obese and left-handed. There were present bilateral choked disks of from 5 to 6 diopters elevation. No defect in the visual fields could be found except general constriction; the right eye was almost blind. The sella turcica was irregularly enlarged.

There being no definite localizing symptoms, a subtemporal decompression was made by Dr. Cushing on the left side, since she was left-handed. The brain was tense, but no evidence of tumor was seen.

Fig. 26 (case 6).—Section stained with hematoxylin and eosin,  $\times 300$ ; spindle-shaped cells running in broad bands in various directions.

*Course of Illness.*—The patient was soon up and around the ward. The decompressed area bulged and was very tense. The choking of the optic disks receded to 2 diopters with so much new tissue formation that vision was still further reduced. As no definite localizing symptoms appeared, she was discharged on Feb. 9, 1916.

*Necropsy.*—The patient died at home on April 2, 1916. The brain was removed by Dr. E. Grey (exact time of post mortem is unknown), and fixed by immersion in 10 per cent formalin. In the right temporal region was a large tumor weighing 130 Gm., attached lightly to the dura mater and completely enclosed by a leptomeningeal capsule. The surface of the brain was pushed inward, and when the tumor was shelled out the convolutions could be seen in the depth of its bed. It was obvious that the tumor had arisen in the leptomeninginx (fig. 25). Its surface was smooth and grossly nodular.

*Microscopic Description.*—Although the gross appearance of the tumor was typical of the ordinary meningioma, its microscopic structure was different.

Portions of the tumor, which had been fixed in formalin, were embedded in paraffin. Sections were stained with hematoxylin and eosin, phosphotungstic acid hematoxylin, Weigert's resorcin-fuchsin, and by Perdrau's method. Frozen sections were impregnated by Cajal's reduced silver method and by Hortega's silver carbonate method.

The tumor was composed of elongated spindle-shaped cells with delicate cytoplasmic extensions (fig 26). The neoplastic cells ran in broad bands in various directions so that they were cut at different angles. The nuclei were oval or elongated with heavy nuclear membrane, fine granules of chromatin and one or two prominent nuclei. Mitotic figures were numerous.

Fig. 27 (case 6).—*a*, section stained by Cajal's reduced silver method,  $\times 850$ ; the spindle shape of the cells is shown by overimpregnation. *b*, Perdrau's method,  $\times 100$ ; showing the reticulum.

No collagen was formed by the neoplastic cells and no elastin. The reticulum was mainly confined to the walls of the vascular sinuses but occasionally was diffusely scattered among the cells (fig. 27 *b*). Fibroglia fibrils could not be demonstrated because of the fixation. The shape of the cells could be seen best in sections excessively impregnated by Cajal's method (fig. 27 *a*).

The microscopic picture was consistent with a diagnosis of fibroblastoma or fibrosarcoma of the leptomeninges.

The next patient is still living (October, 1927), and no signs of tumor outside the nervous system have appeared.

CASE 7.—*Fibrosarcoma of the right temporal region. Right osteoplastic exploration. Secondary operation with partial extirpation of tumor. Radiotherapy.*

*History.*—John F., aged 19, referred by Dr. Daniel McCann of Bangor, Me., was admitted to the hospital on Dec. 17, 1926, complaining of failing vision, vomiting and headache.

He had been well, with the exception of an ophthalmia at birth which had left defective vision in the right eye, until September, 1926. At this time he noticed that his vision again was failing. On November 1, he began to have daily attacks of vomiting, which continued until about December 1, when headaches set in and the vomiting became more persistent. For the last few days, he noted that he was apt to run into objects on his left side without seeing them.

On admission, there was found bilateral choked disks of from 5 to 6 diopters elevation, left homonymous hemianopsia, nystagmus, especially on looking to the left, and defective vision in the right eye from cloudy media.

On Dec. 27, 1926, a right osteoplastic exploration was made by Dr. Cushing with immediate subtemporal decompression. The brain was under tension, the convolutions flattened, the sylvian fissure displaced upward, but no tumor was found.

*Course of Illness.*—The patient recovered slowly from the operation and was discharged on Jan. 16, 1927. At this time headaches and vomiting were entirely relieved, the decompressed area was bulging but soft, and the swelling of the optic disks had subsided to 2 diopters. The left hemianopsia persisted, and in addition, there was a slight left hemiparesis.

One roentgen treatment had been given on January 14.

He felt well for about a month, and then a progressive weakness of the left arm and leg began, and by March 15 the left arm was practically useless. He had two convulsive attacks localized to the left foot. He also had what seemed to have been visual hallucinations in which he saw yellow lights before his eyes for a few seconds.

*Second Admission.*—April 28, 1927: At this time the decompressed area was bulging and tense, there was slight swelling of the optic disks, a left hemiplegia and hemianesthesia and a left homonymous hemianopsia.

On May 10, the old operative wound was reopened and the bone flap removed. The temporal lobe protruded markedly. It was incised, and in doing so the temporal horn of the ventricle was opened. On the inner wall of the ventricle could be seen a reddish discoloration indicating an underlying tumor. The tumor was soft, and a large amount was removed by suction. Some pieces were taken at various times for microscopic study. It was impossible to make a clean enucleation because of the great depth in the brain.

There was improvement in the strength of his left arm but the decompressed area was very tense and he complained of stiffness of the neck, so that on May 18 the wound was reopened and a great deal of clotted blood and degenerated brain tissue were removed, as well as some neoplastic tissue which had been meanwhile extruded.

He recovered promptly and was discharged on June 5, 1927, with a left hemiparesis, hemianopsia and hemianesthesia, but was comfortable and able to walk without assistance.

He improved at home and was able to go to a summer camp, caring for himself and even rowing a boat on the lake. He was examined on October 11, at which time the decompressed area was bulging and tense; the left spastic hemiparesis persisted, but he was able to walk alone and was comfortable, with no

headaches or vomiting. There was a left lower quadrantal defect in the left visual field; the right visual field could not be examined because of imperfect vision. The left optic disk was pale, with hazy margins and no measurable elevation.

*Microscopic Description.*—Blocks were cut from various parts of the growth, fixed in Zenker's fluid and in 10 per cent formalin, and embedded in paraffin. Sections were stained with hematoxylin and eosin, neutral ethyl violet-orange G, aniline blue-orange G, by Verhoeff's method for elastin and by Perdrau's and Foote's methods for reticulin.

Dr. S. B. Wolbach stated in his report on this tumor that "for the first time I am obliged to return a diagnosis of fibrosarcoma." The tumor was seen to be composed of streams of spindle-shaped cells running in various directions so that they were cut lengthwise, crosswise and at all angles in different parts of the

Fig. 28 (case 7).—Section stained with methylene blue-eosin,  $\times 300$ ; characteristic microscopic picture of a spindle cell sarcoma.

sections (fig. 28). The cells had delicate cytoplasm, staining lightly with eosin, and oval or elongated nuclei. The contour of the nuclei was rarely regular but usually angular or crenelated. The nuclear membrane was heavy; the chromatin was dustlike so that the nuclei had a vesicular appearance and the nucleoli were prominent. Mitotic figures were numerous. Vascular sinuses lined with a single layer of endothelial cells were scattered throughout the tissue.

In the more cellular parts of the tumor only delicate reticulin fibrils could be found between the cells (fig. 29 a) but in degenerated areas considerable collagen was formed. Delicate fibroglia fibrils were present in different parts of the tumor (fig. 29 b). No elastin was seen.

The tumor had, therefore, the typical structure of a fibroblastoma or fibrosarcoma.

I have seen another similar tumor from Dr. Cushing's early Johns Hopkins series. It was a huge growth weighing 341 Gm., and was removed in 1904 from the right parieto-occipital region of a 5 year old boy. Since insufficient tissue has been preserved for a complete restudy it is only mentioned here.

#### ALVEOLAR SARCOMA

In rare instances there may arise in the brain primary tumors which reproduce the structure of the small round cell sarcoma, the spindle cell or fibroblastoma and the melanosisarcoma of the peripheral

Fig. 29 (case 7).—*a*, section stained by Perdrau's method,  $\times 150$ ; delicate newly formed reticulin fibrils scattered between the neoplastic cells. *b*, neutral ethyl violet-orange G,  $\times 850$ ; very delicate fibroglial fibrils.

connective tissues. I have not found a sarcoma of alveolar type which was certainly primarily intracranial. The tumor in the following case is clearly of this type, but may be metastatic. This case is inserted to show how easily this type of tumor may be distinguished microscopically from a glioma, principally from the study of its reticulum.

**CASE 8.**—*Hemorrhagic tumor in the region of the left basal ganglia, with the microscopic structure of an alveolar sarcoma (metastatic?). Suboccipital operation. Fatality. Necropsy.*

**History.**—On Nov. 9, 1923, George H., aged 5, referred by Dr. W. E. Dake of Rochester, N. Y., was admitted to the hospital complaining of headache and vomiting.

He had been a healthy child until August, 1923, when he became listless and complained of being tired. A month later, he began to have headaches, accompanied by vomiting, which had continued since that time. Recently, in severe attacks his head would be retracted, his arms tonically flexed and his fists clenched. Enuresis was frequent, but there were no clonic convulsions.

On admission, the patient was drowsy and apathetic, preferring to remain in bed, for the assumption of an erect position caused severe headache. There was suboccipital tenderness to pressure and some stiffness of the neck. The venules of the eyelids were distended. The optic disks were choked, with from 3 to 4

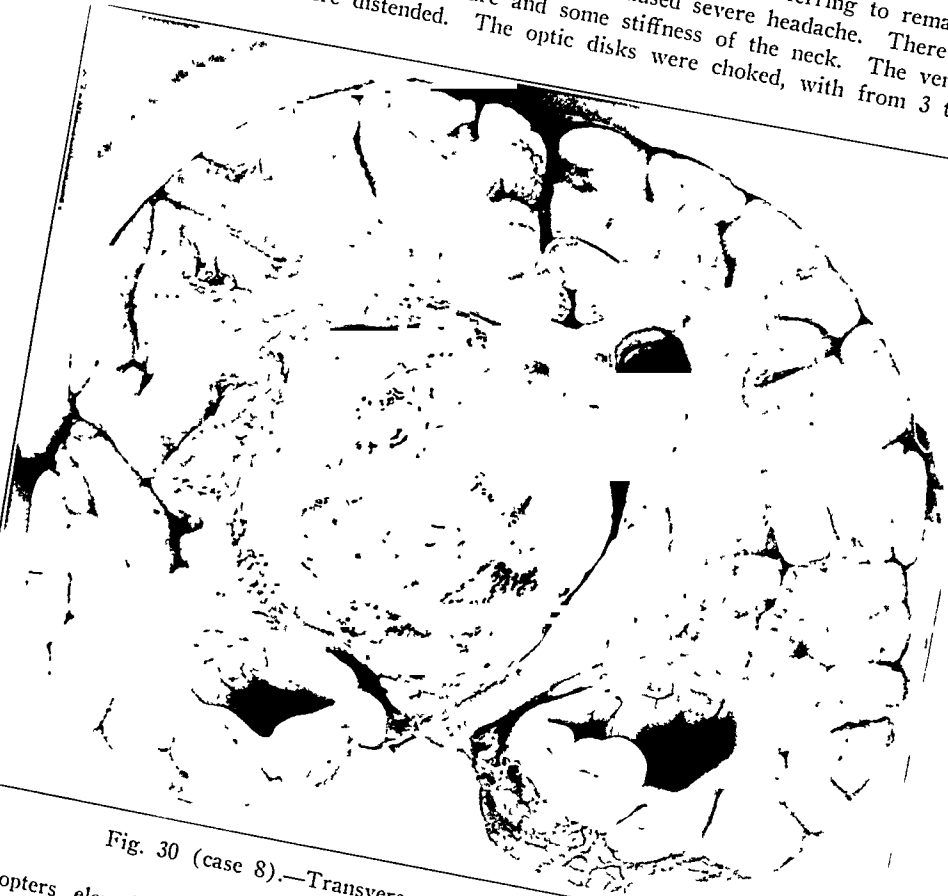

Fig. 30 (case 8).—Transverse section through the tumor.

diopters elevation. There was some hypotonicity of the extremities but no incoordination and no nystagmus. There was a slight right facial weakness. Percussion of the skull gave a cracked pot sound, and a roentgenogram showed the cranial sutures to be dilated.

On November 21, a suboccipital operation was performed by Dr. Cushing. Before the dura mater was opened, the occipital horn of the left lateral ventricle was punctured and abundant xanthochromic fluid escaped. The same yellow fluid was obtained from the posterior cistern. No tumor was found, and the cerebellar hemispheres appeared normal.

*Course of Illness.*—The patient developed a hyperthermia, did not regain consciousness, and died the following day.

*Pathologic Examination.*—A general necropsy was not allowed, but the brain was removed after injection with 10 per cent formalin through the carotid arteries. Externally, only flattening of the cerebral convolutions could be seen, but when the brain was sectioned there was disclosed a hemorrhagic tumor 5 cm in diameter arising apparently in the region of the left basal ganglia but pushing the third ventricle and velum interpositum over to the right so as to occupy practically the center of the intracranial cavity (fig. 30). If primarily in the brain, it must have arisen from the connective tissue of the velum interpositum. The choroid plexuses of the left lateral and third ventricles lay free on its surface.

*Microscopic Description.*—Blocks of the tumor, which had been fixed in formalin, were embedded in paraffin. Sections were stained with hematoxylin and

Fig. 31 (case 8).—Section stained with hematoxylin and eosin,  $\times 300$ . The nuclei are of connective tissue type. The cells of the stroma are not distinct from the other neoplastic cells.

eosin, phosphotungstic acid hematoxylin, by Perdrau's method, by Weigert's resorcin-fuchsin method and by van Gieson's method.

The tumor was much degenerated and riddled with hemorrhage, but where the structure was fairly normal it could be seen to be composed of alveoli of rounded or irregular cells separated by septums of reticular tissue (fig. 32 *b*). A little collagen was present around the vascular sinuses in the cellular parts and was much more abundant in certain areas of sclerosis where the alveolar cells were degenerating or absent. No elastin and no fibroglia were seen. The reticulin and collagen seemed to be formed by the neoplastic cells. The nuclei along the strands of reticulin were sometimes more elongated but not otherwise different from the nuclei of the alveolar cells. The latter had irregularly oval or spherical

nuclei with heavy nuclear membranes, delicate granules of chromatin and prominent nucleoli (fig. 31). Mitotic figures were numerous.

The structure was that of an alveolar sarcoma. No other nodules of tumor were found in the brain. The margin of the growth was nodular and fairly sharp, but there was no capsule. A narrow zone of interpenetration of the neoplastic and cerebral tissue existed and at one point the neoplastic cells followed the vessels to a considerable distance into the brain. At the margin of the tumor might be found numerous scavenger cells and petechial hemorrhages. The cerebral tissue near the tumor was slightly flattened and condensed. The tumor, therefore, seemed to be growing both by pushing aside and by penetrating and destroying the nervous parenchyma.

Fig. 32.—*a*, copied from Romano, showing the arrangement of the reticulin in a sarcoma. *b* (case 8), Perdrau's method,  $\times 100$ ; arrangement of the reticulin is that of an alveolar sarcoma.

The common arrangement of the reticulum in alveolar sarcomas may be seen in the illustrations accompanying the articles of Romano (fig. 32 *a*) and Speciale. It will be seen to be exactly similar in the tumor just described (fig. 32 *b*).

The study of the reticulum of tumors was begun by the use of the digestion method as early as 1900, by White, and a similar study was made by Seelig, in 1907, of the distribution of reticulum in small round cells and lymphosarcomas. The latter author showed clearly the intimate network of reticulin in these tumors forming whorls, or lattice-work, radiating from focal points. The digestion method, however, does not

distinguish sharply reticulum from collagen and the study was renewed by the use of silver impregnations with the Bielschowsky method and its modifications.

The first to use silver methods for the study of reticulum in tumors seems to have been Kuru, but the Italians have made most use of them in a series of articles by Righetti, Martelli, Niosi, Licini, Romano, Speciale and others. The latter used the tannic silver method of Achúcarro. In this country, the study has been taken up by Foot and Day.

The upshot of all these studies seems to be that the arrangement of the reticulum tends to be different in sarcomas and in carcinomas but

Fig. 33.—Neuro-epithelioma cerebri: *a*, Achúcarro,  $\times 80$ ; *b*, hematoxylin and eosin,  $\times 300$ . Stroma of connective tissue; note the ease with which the cells of the stroma are distinguished from the neoplastic cells.

is not pathognomonic. However that may be, there is no doubt that the arrangement of the reticulum in gliomas is different from that seen in sarcomas. Foot and Day remarked that the glioma, neuroblastoma and ganglioneuroma show no reticulum other than that of their blood supply. This statement is true in general, but, as Wolbach has pointed out, there may be in medulloblastomas (neuroblastomas of Wright) a considerable stroma of reticulin. It is exceedingly rare, however, that a sufficient reticulum exists to make the differential diagnosis between medulloblastomas and sarcomas difficult; even in this case the distinction

may be easily made by the fact that in the medulloblastomas and neuro-epitheliomas, where the most abundant stroma occurs, the nuclei of the cells of the reticulum are clearly distinguishable from those of the neoplastic cells (fig. 33 *b*) which is not true in sarcomas. Moreover, the distribution of the reticulum in gliomas is different, consisting only of delicate strands running from one capillary to another, similar to the Robertson's fibrils of the normal brain (fig. 33 *a*). Of course, the overgrowth of fibroblastic tissue which occurs in the case of extensive degeneration in tumors of neuro-epithelial origin must be carefully excluded in making a differential pathologic diagnosis.

#### SUMMARY

I have tried to show by the description of a series of rare tumors how true sarcomas of the brain may arise, and to follow, as well as the limited material would permit, their structure and evolution. Although all of the tumors reported were not proved by necropsy to be primarily intracranial, I have used the doubtful cases to point out the structural characteristics by which sarcomas may be distinguished from gliomas.

Although all these tumors must arise from the leptomeninx or its derivatives, their microscopic structure is exceedingly diverse. The various types which they assume for the most part emphasize the kinship of the pia-arachnoid with the extraneural connective tissues. Only the occurrence of melanomas might be considered to argue in favor of a neuro-ectodermal origin of these tumors, in case the melanin-bearing cells differentiate directly from the meningoblasts. However, in the absence of any direct embryologic observations on the development of the meningeal melanophores, it is possible that they migrate into the pia-arachnoid as they are said to do into the choroidal coat of the eye.

Tumors of the type I have described are exceedingly rare, have no constant clinical manifestations, and form a very small percentage in any statistics of cases of tumors of the brain. They are interesting largely from the standpoint of theoretical pathology.

## THE HYPOPHYSIS OF THE PORPOISE (*TURSIOPS TRUNCATUS*)\*

GEORGE B. WISLOCKI

*Cetacea* constitute a group of mammals in which the soft tissues have been studied only superficially. The size of these mammals and the conditions under which they are caught make proper preservation of their bodies for dissection almost impossible, not to speak of the difficulty of actual shipment to a laboratory and subsequent storage there. Moreover, in the case of most of the larger whales, so much time elapses between the killing of the animals and the completion of an autopsy that, even in the field, it is difficult to obtain the viscera fresh and properly fixed. The magnitude of such an undertaking is described by Turner. At Longniddry, in 1872, he helped to cut up a great stranded finner whale which was 78 feet, 9 inches long, from which a fetus measuring 19 feet, 6 inches was removed.

The dolphins or porpoises constitute the smallest of the whales. They are abundant along the coasts and estuaries of all continents, but they are seldom pursued and caught by man. From time to time, however, fisheries have existed in Europe and America where porpoises were captured to obtain the oil from their heads, which has considerable commercial value. At one station in the United States, a group of investigators from the Johns Hopkins University had an unusual opportunity to perform ten autopsies on porpoises. These animals, of the species *Tursiops truncatus*, were from 7 to 8 feet (213 to 244 cm.) long and weighed approximately 600 pounds (273 Kg.). They were sufficiently small, therefore, to allow tissues to be obtained and preserved in a brief time.

Six skulls were opened during an afternoon, and the brains were removed by a team of workers. At the same time, the hypophysis was uncovered and observed. The pituitary glands presented such an unusual appearance that a number of them were carefully taken out and fixed in formalin bichromate or Bouin's fluid.

The hypophysis of *Tursiops* lies in an extremely shallow depression of the sphenoid bone. The anterior clinoid processes form a slight transverse bony ridge bounding the sella anteriorly. The posterior clinoid processes, however, are absent, the sella being demarcated posteriorly by a smooth, scarcely perceptible transverse elevation. The hypophysis lies flattened out in this shallow depression. It is enclosed by a capsule of dura mater, of which one layer covers the floor of the

---

\* From the Department of Anatomy, Johns Hopkins University.

sella turcica and the other constitutes the diaphragma sellae. The diaphragma, to be described later, bears an unusual relation to the neural and epithelial portions of the gland.

The hypophysis is a flattened, rectangular organ attached to the diencephalon by a stalk. On removing it from the base of the brain, one discovers at once that it consists of two rather independent parts: (1) a rectangular portion, which is extremely red and vascular, and (2) a smaller overlying portion, which is ovoid and comparatively pale and avascular. The two parts are separated from one another by a fold of dura, a portion of the diaphragma sellae which is split into two laminae to form a pocket accommodating the smaller lobe and separating it from the larger one. The larger, vascular lobe, is, obviously, grossly homologous to the pars distalis of other mammals, the smaller lobe homologous to the processus infundibuli. The two are united in the porpoise in one region only, namely, at the infundibulum. The epithelial portion of the gland, at the point (fig. 1, *A* and *B*), clasps the infundibulum by a thin lamina, enfolding the neural stalk in the form of a collar, incomplete or open on the posterior surface. The diaphragma sellae prevents further union of the epithelial and neural derivatives. As the dura spans the sella, it separates into two sheets, one extending dorsad to the processus infundibuli, the other spreading out beneath the neural lobe into the recess between it and the underlying pars distalis (fig. 1, *B*). The dorsal lamina is perforated by the infundibulum, and the ventral lamina, by an extension of the epithelial portion of the hypophysis which grows upward to ensheath the infundibulum. It is obvious, however, that most of the buccal portion of the gland remains anatomically separated from the neural lobe.

The hypophysis is not unusually large for the size of the animal. The larger lobe, the pars distalis, measures approximately 2 cm. in width, 1.5 cm. anteroposteriorly and 0.5 cm. in thickness, whereas the corresponding measurements of the neural lobe are 10, 7 and 3 mm., respectively.

When sections of the hypophysis are examined under the low power of the microscope, other peculiarities of structure are observed. The pars distalis, or anterior lobe, is composed of cords of cells separated by a reticulum and so arranged as to constitute lobules. In each lobule, the characteristic cellular elements are arranged in a somewhat definite manner (fig. 3, *A*). In the pars distalis, the cords of cells, or lobules, contain neither colloid or cysts.

The outgrowth from the anterior lobe, which extends upward as a thin lamina through the gap in the diaphragma sellae to join the infundibulum, is composed, on the other hand, exclusively of follicles containing colloid (fig. 4, *B*). The follicles of the juxtaneural portion

Fig. 1—*A*, the adult hypophysis of the porpoise (*Tursiops truncatus*) seen from the dorsal surface, with the meninges removed. The well marked separation of the processus infundibuli from the pars distalis can be observed. The juxtaneural part of the buccal portion of the hypophysis embraces the infundibular stalk as a thin lamina. In the fresh specimen, the anterior portion of the gland is deep red, whereas the neural portion is pale. *B*, schematic representation of a mid-sagittal section through the hypophysis, showing the almost complete separation of the two lobes. The dural sheath surrounding the lobes is represented by a dotted line. A hypophyseal cleft, as well as a pars intermedia, is lacking. The infundibular recess is a slitlike cavity extending for a short distance into the infundibular stalk;  $\times 3$  *Inf.*, infundibulum; *P. i.*, processus infundibuli; *P. d.*, pars distalis, and *P. j.*, pars juxtaneuralis.

with their uniform and characteristic structure merge gradually into the lobules of the pars distalis at the juncture of the juxtaneural lamina and the body of the buccal portion. In this zone of transition, the amount of colloid in the follicles decreases. The cellular mantle increases in thickness, until the follicles become completely cellular, with the cells arranged solely as in the anterior lobe. Thus, the pars buccalis consists of two microscopically differentiable portions separated by a transition zone. These two characteristic histologic segments are homologized most readily with the pars tuberalis and pars distalis of other mammals.

An intermediate portion of the buccal derivative, a pars infundibularis, is entirely lacking. A demonstrable residual lumen of Rathke's pouch is not present, either as a cavity or in the presence of cysts. Moreover, there is not a special arrangement of the cells characteristic of the intermedia in other mammals. A mammalian hypophysis in which the intermediate portion is lacking, as in the porpoise, is unusual. In man, the cleft separating the intermedia from the pars distalis is known to disappear frequently in the course of growth or to become converted into cysts with a gradual obliteration of the intermedia. In all other mammals, however, the persistence of the cleft and its characteristic cells is described. In lower vertebrates, particularly in birds, the absence of the cleft and of the pars intermedia is the rule. Lacking knowledge of the early developmental stages of the porpoise, one cannot determine how early the cleft resulting from the invagination of Rathke's pouch becomes obliterated. In the adult porpoise, however, the buccal portion of the hypophysis consists of only an anterior lobe and a pars tuberalis.

The finer structure of these two parts differs somewhat from the arrangement and character of the cells encountered in the hypophyses of other mammals. The anterior lobe exhibits a pronounced lobulation resulting partly from the arrangement of the cells which constitute the lobules, and partly from the disposition of the reticulum surrounding the lobules (fig. 3 *A*). The anterior lobe is extremely vascular, containing sinusoidal capillaries and veins. The endothelium of the vessels rests on a rich layer of reticulum fibers and cells which support the blood vessels and serve as a line of demarcation for the cords or lobules of hypophyseal cells.

The cells within the lobules show a fairly definite relationship to one another and to the surrounding vessels. There are three characteristic types of cells distinguishable in the anterior lobe, as in other mammals: eosinophil cells, basophil cells and chromophobe cells. The majority of the basophil and chromophobe cells have a nucleus which is vesicular and rather large and possesses an open chromatin network. A lesser number of cells have a nucleus which is smaller and pyknotic, therefore staining more deeply; the chromatin network cannot be dis-

Fig. 2.—Drawing of a lobule of the pars distalis showing the arrangement and character of the cells; *ac.*, acidophil cell; *bas.*, basophil cell; *chr.*, chromophobe cell; *str.*, stroma, and *tr.*, transitional cell. Mallory's connective tissue stain. Basophil and eosinophil cells occur on the periphery of the lobule, whereas chromophobe cells predominate in the center. Many basophils exhibit red cytoplasmic granules and several cells show accumulations of larger red granules in their cytoplasm, suggesting transitional stages between basophilic and acidophilic cells.  $\times 700$ .

tinguished. The eosinophil cells exhibit only the vesicular type of nucleus.

The basophil and eosinophil cells do not show a constant distribution throughout the anterior lobe. The eosinophil cells are somewhat more numerous in the interior of the gland than in its periphery. Moreover, the eosinophil cells often occur in nests which constitute almost the whole cellular content of a cord or lobule. The hypophyses described are from male porpoises only. The possible changes concurrent with an estrual cycle or with pregnancy, therefore, do not have any bearing on the discussion.

In the individual lobules constituting the hypophysis of the porpoise, the arrangement of the three types of cells is fairly constant. Each lobule or cord has a peripheral row of cells and a group of cells in the center (figs. 2 and 3, *A* and *B*). The rim of cells consists invariably of basophil cells, eosinophil cells or a mixture of the two dependent on the character of the lobule. These two elements, therefore, are close to the blood vessels. On the other hand, the center of the lobule is occupied largely, although not exclusively, by chromophobe cells (figs. 2 and 3, *B* and *C*). There are occasional eosinophil as well as basophil cells in the centers of the lobules. In several hypophyses, also, the centers of the lobules in some parts of the anterior lobe are occupied by large, ordinary fat cells (fig. 3, *D*).

In sections colored with Mallory's connective tissue stain, a curious staining of many of the basophil cells is observed. The eosinophil, basophil and chromophobe cells are clearly and sharply stained in these sections. Examination of many basophil cells under the oil immersion lens reveals, in addition to a deep blue coloration of the granules of the cytoplasm, that the cells are dusted with small red granules (fig. 2). In most instances, these granules are scattered throughout the cytoplasm, but in others they exhibit a tendency to be gathered into a cluster around, but predominantly to one side of, the nucleus. In other basophils, the acidophilic granules are larger and more abundant giving a completely acidophilic character to a portion of the cytoplasm (fig. 2). Conversely, a few decidedly eosinophilic cells possessing basophil granules in the neighborhood of the nucleus have been observed.

This staining of many of the granular cells in sections treated with Mallory's connective tissue stain is unusual.

The occurrence of both types of granules in a single cell has not been described in the hypophyses of other mammals. It suggests strongly the possibility that the fine acidophilic granules occurring in the basophils may be antecedents of the eosinophil granules of the typical acidophil cells. It raises the question as to whether the two types of cells are only different functional stages of a single cell, an hypothesis which is advanced by some observers, but

Fig. 3.—*A*, a portion of the pars distalis, showing a pronounced lobular arrangement with a tendency of the chromophobe cells to occupy the centers of the lobules;  $\times 195$ . *B*, a lobule with basophil cells on its periphery, and chromophobe and a few eosinophil cells in the center;  $\times 500$ . *C*, a lobule in which eosinophil cells occupy the periphery, with chromophobe cells in the center;  $\times 500$ . *D*, a portion of the pars distalis showing fat cells occupying the centers of the lobules;  $\times 195$ .

denied by others. The presence of granules of both types in the same cell certainly suggests a transitional phase between basophils and eosinophils and is sufficiently interesting to make further work on the hypophysis of the porpoise desirable.

From this standpoint also, the other observation on the pars anterior may be important, namely, that the granular cells have a tendency to peripheral distribution in the lobules, whereas the nongranular cells are restricted to the interior of the lobules. Consequently, the cells producing granules, which are most likely the secretory cells, are nearest to the periphery and closest to the vascular sinuses, the only possible avenues of escape of secretion from the pars distalis. In other material, observers have described the presence of eosinophil granules lying free in the sinuses. In the present specimens, eosinophil granules were also observed in the vascular spaces, whether as the result of artefact or of actual discharge, it is impossible to say. It seems significant, however, that the eosinophil cells in most of the lobules are in close proximity to the perivascular tunic.

On examination of the zone of transition between the anterior lobe and the pars tuberalis, the first thing noted is the appearance of one or more droplets of colloid between the chromophobe cells in the interior the drops of colloid increase in size. The eosinophil cells in the periphery of the lobule dwindle in number, as do also the basophil cells, though more gradually. For the first time, chromophobe cells now make their appearance in large numbers along the rim of the lobule, until, as the pars distalis is reached, the eosinophil and basophil cells have all been replaced by chromophobe cells.

The typical structure of the pars tuberalis consists of follicles containing colloid which are lined by one row, occasionally by two rows, of chromophobe cells (figs. 4, *B*). Some of the follicles appear to be so distended with colloid that the limiting epithelial cells are cuboid in shape or even shorter. The uniformity in size and distribution of the follicles is characteristic. The follicles are dispersed in a rather loose reticular stroma containing numerous thin-walled sinusoidal blood vessels. The number of these vessels is in striking contrast to the relative avascularity of this portion of the gland in the human and other mammalian hypophyses.

Sections reveal the line of fusion of the pars tuberalis with the infundibulum. The line of junction is sharply defined, as can be seen in sections stained with Mallory's connective tissue stain. The deeply stained reticulum surrounding the follicles and vessels of the pars tuberalis does not intermingle with the relatively pale-staining, neuroglial groundwork of the neural tissue. When a vessel penetrates the neural stalk from the pars tuberalis, it is accompanied by a deep-staining perivascular sheath, an extension from the stroma of the epithelial tissue.

Fig. 4.—*A*, the junction of the pars distalis with the pars tuberalis; colloid drop-lets appearing in many of the lobules should be noted; eosinophil and basophil cells are still abundant;  $\times 195$ . *B*., the pars tuberalis and the adjacent infundibulum with the follicles containing colloid which are characteristic of this region; the pars tuberalis shows marked vascularity; the sharp line of demarcation between the pars tuberalis and the pars nervosa can be seen;  $\times 195$ . *C*, another portion of the pars tuberalis, illustrating the size and shape of the follicles, and the pronounced vascularity of the tissue;  $\times 195$ . *D*, a portion of the interior of the processus infundibuli showing numerous sinusoidal vessels; the structure of the pars neuralis appears to be quite uniform and simple, consisting solely of these vessels and neuroglial cells;  $\times 195$ .

Histologically, the pars nervosa is simple and uniform in character. It is composed of fine meshed neuroglial tissue in which blood vessels occur rather abundantly. Nerve cells are not encountered. Hyaline bodies or droplets of colloid are not present in the posterior lobe, nor are glandlike, epithelial sprouts or isolated epithelial cells seen to invade the infundibulum at the line of junction with the lamina of the pars tuberalis. The vascular supply of the pars nervosa is certainly greater than it is in other mammals. The interior of the processus infundibuli appears in places to be honeycombed by thin-walled, anastomosing, sinusoidal blood vessels (fig. 4, *D*).

The infundibular cavity, consisting of a slitlike cleft extending from the third ventricle into the infundibular stalk, fails to penetrate the processus infundibuli, which is solid (fig. 1, *B*). The cavity is flattened anteroposteriorly and is lined with a single layer of ependymal cells.

#### COMMENT

Observations on the hypophysis of the porpoise emphasize the variable morphology of this structure in mammals. These differences from the customary structure of other mammals relate to the gross, as well as to microscopic, anatomy of the gland.

The underlying significance of the differences in the mammalian hypophysis remains obscure. The morphology of an endocrine gland of this type might be thought relatively constant. The adaptation of form to function in mammals is readily understood in reference to the purposeful adaptation of the skeleton and extremities to different postures and modes of progression, or of the stomach and intestines to the exigencies of digestion. On the other hand, in organs which are not obviously subjected to direct environmental stimuli, the factors which operate to produce the varying morphology within different species are difficult to elucidate.

It is important, however, to bear in mind that the hypophysis of mammals differs considerably in its structure. The whales, in many respects, highly differentiated, and aberrant mammals, adapted to marine life, may have a hypophysis peculiarly modified to meet their special needs. The morphology of the hypophysis common to the group of mammals, as well as the special features existing in individual species, will have to be considered in the attempt to correlate the form of the structure with the biologic functions controlling and regulating growth and reproduction.

#### SUMMARY

1. In the porpoise, the processus infundibuli is separated anatomically from the buccal portion of the hypophysis by a fold of dura, a portion of the diaphragma sellae.

2. The pars intermedia and hypophyseal cleft are completely lacking in the adult porpoise, the pars buccalis consisting solely of a pars tuberalis and of a pars distalis.

3. The pars distalis consists of lobules which are much more pronounced than in other mammals. These lobules contain three types of cells similar to those customarily recognized in the mammalian hypophysis. With Mallory's connective tissue stain, however, many of the basophils and a few of the eosinophils contain both acidophilic and basophilic granules. These cells suggest transitional forms between basophils and eosinophils. Within each lobule, the cells are arranged in a somewhat definite relationship. The periphery or rim of each lobule is formed solely by a row of granular cells, whereas the center of the lobule consists chiefly of chromophobe cells, besides occasional eosinophil, basophil or fat cells.

4. The pars tuberalis is composed of follicles containing colloid. The epithelial cells lining the follicles are chromophobe and usually in single layers.

5. The pars nervosa is composed throughout of neuroglial tissue, supporting blood vessels. Nerve cells, hyaline bodies or droplets of colloid are not present. The infundibular cavity does not penetrate the processus infundibuli.

# IMPROVED METHODS FOR NEPHROPEXY AND FOR EXPOSURE OF THE KIDNEY

FREDERIC É. B. FOLEY

Nephropexy, a procedure once well regarded and frequently employed, has become almost an obsolete operation, and through no fault of its own. In spite of this fate, two facts on which the rationale of the operation is based remain true: (1) nephroptosis directly and solely responsible for obstruction, painful symptoms and persisting infection does occur; (2) the condition may be permanently corrected by appropriate surgical procedure. Failure to meet the diagnostic and operative requirements imposed by these two facts has given rise to incorrect conclusions in three different groups of cases, and has earned for nephropexy its present disrepute.

In the first group of cases there is no significant abnormality of the upper urinary tract, the loose kidney being a mere incident and of no consequence. No other anatomic change in kidney or ureter is present and the symptoms are of extra-urinary tract origin, erroneous conclusions to the contrary being due to inexact methods of diagnosis. In this group, the operation has been done most frequently for relief of abdominal pain: in one case mild, vague and poorly localized; in another, severe, well localized, and much like renal colic; but of renal or ureteral origin in neither. It is nothing against nephropexy that it fails to relieve the symptoms of disease of the gallbladder, appendicitis, Pott's disease or the symptoms of the various other conditions actually responsible in these cases. The operation has even been employed for relief of nervousness, headache, "poor digestion," and vagaries for which the innocent loose kidney is responsible only in the imagination of the surgeon.

In the second group of cases the symptoms are of urinary tract origin, and significant abnormality of these structures is present and directly responsible for symptoms. Pain, persistent infection, effects on urination and changes in the urine, one or all may be present. Failure to apply rigorous diagnostic criteria permits the loose though innocent kidney to be accused, but leaves the actually responsible lesion unrecognized. Nephropexy will not remove a ureteral stone, dilate a stricture or correct any of the various other lesions, some of them very obscure perhaps, which may be producing the symptoms in such cases.

In the third group, nephroptosis itself is solely and directly responsible for symptoms. This conclusion is warranted only through painstaking and comprehensive clinical investigation, which not only demonstrates the symptoms to be of upper urinary tract origin but definitely assigns nephroptosis as their cause. In this, the only group in which

there is excuse for the operation, wrong conclusions have been arrived at and further disrepute has been earned for nephropexy by failure to meet the requirement to employ an appropriate surgical procedure. Either a method for renal fixation fundamentally wrong and incapable of accomplishing its end has been employed, or through technical faults on the part of the operator, the purpose of a good procedure has been defeated.

Certain cases may present unusual difficulties which make proper positioning of the kidney and ureter impossible or render incapable of execution important details of the method it is sought to employ. Failure here only acknowledges that unusual technical difficulties may impose limitations on the operation. These exist for most surgical procedures.

Apart from failures arising from the sources already enumerated, and incorrect conclusions based on them, there is nothing which entitles nephropexy to its present disfavor. A properly designed operation for fixation of the kidney based on correct conceptions of tissue reaction and repair and employing sound surgical principles will accomplish its purpose for the same reasons that a uterine malposition may be corrected or that a hernia may be repaired. Only by such a procedure employed exclusively in cases to which rigorous diagnostic criteria have been applied may nephropexy be properly appraised.

The method for fixation of the kidney here described is not offered as the best method. It is merely asserted that in cases in which exacting methods demonstrated nephroptosis to be the cause of symptoms it has regularly given excellent results and has appeared to fix the kidney permanently. So far as it has been possible to determine, the method in some measure is new and original. On this ground, however, no claims are made for it as it merely adapts to a certain scheme of procedure and technical accomplishment principles in no way original. It seems sound in surgical and mechanical principles and employs no flaps, trick sutures or other bizarre foibles in which the literature of nephropexy abounds.

In the evolution of this operation for nephropexy it became apparent that the dissection employed as the first step in the procedure gave an unusually fine exposure of the kidney. Particularly in obese subjects and in operations ordinarily made difficult by old inflammatory infiltration of the perirenal structures it was found to facilitate exposure remarkably and gave access to the vessels, the pelvis and upper ureter with considerably less impediment than procedures previously employed. Forthwith, this method of exposure was adopted as routine for all operations on the kidney on the Urologic Service at the Ancker Hospital and in private practice, and has been so employed continuously during the past five years. The experience of my associates and myself with these methods in several hundred operations recommends them for description.

Figure 1

Figure 2

## SURGICAL PROCEDURE

*Position of Patient.*—For exposure of the kidney there is no detail more important than the position and fixation of the patient on the operating table. No amount of operative skill will compensate for lack of proper attention to this.

Figures 1 and 2 show the arrangement which has been employed. The table mattress lies over the mechanical kidney elevator or bridge, and serves to protect the patient from trauma by its edges. The plane of a midfrontal section of the patient's body is made exactly vertical on the table. The patient is so placed that the edge of the bridge toward the foot of the table crosses the flank just above the crest of the ilium. The under part of the thigh is flexed and so serves to

Figure 3.

steady somewhat the position. Two pillows are placed between the thighs and legs, the fully extended extremity of the side of operation lying on them. A girth is drawn securely taut over the leg just below the knee. The under shoulder girdle is drawn toward the head by traction on the arm, thus stretching somewhat the flank and straightening it out by correcting the tendency to anterior flexion of the lumbar spine. The patient's back is close to the operator's edge of the table. As in a vise the body, with its frontal plane in vertical position, is supported by the two flanges attached to the bridge, the long one against the abdomen, the short one against the back.

*Incisions.*—For nephropexy, the incision shown in figure 3 is employed. It is not carried up into the costovertebral angle, as in operations for other purpose, but

begins well anterior to the edge of the sacrospinalis muscle, thus leaving intact the wall of the renal fossa in which the kidney for fixation is to be placed. Beginning below and parallel to the twelfth rib, the incision is extended forward the required length.

For procedures other than nephropexy, preservation of an intact renal fossa is not important and much facility is gained by extending the incision well up into the costovertebral angle as shown in figure 4. The arcuate ligament stretching across the angle from the twelfth rib to the transverse process below it may be divided later and will permit considerable upward retraction of the rib and wide opening of the wound.

Figure 4.

Division of skin and subcutaneous fat upward parallel to the spine and across the rib or articular process will remove the interference they offer to wide retraction of the deeper layers. The incision may be continued into the front of the abdomen as required by the stature of the patient or the individual requirements of the case. For nephro-ureterectomy, it has been extended down into the lower quadrant somewhat in the form of a Gibson incision.

Free division of all muscles is made with exposure of the lumbodorsal fascia (fig. 5). This fascia is incised for the most part parallel to its fibers. The twelfth subcostal nerve is found coming through the fascia near the middle of the incision. Care should be taken not to include the nerve in a ligature or otherwise injure it. The forward part of the incision is placed well above the emerging nerve so that in

its downward course it will not have to bridge the incision and so form an obstructing cord. In the upper part of the incision, where the nerve lies on the inner aspect of the lumbar fascia and muscles, it may be lifted out of its bed and pushed away as the incision in the fascia is extended upward. This also permits free and rapid division of the arcuate ligament well up into the angle if this is required.

*Exposure.*—The first most important detail of the special technic of exposure lies in taking advantage of a natural line of cleavage between the pararenal or Gerota's fascia and the muscles posteriorly on which it lies.

Previous to adoption of the present method it had been customary to incise immediately the pararenal fascia with exposure of its contained mass of perirenal

Figure 5.

fat, the kidney being approached by blunt dissection through this. From textbook descriptions and observation of numerous operations in other hands, such a method of approach appears to be employed generally. In the technic recommended here, such a line of procedure is carefully avoided. By comparison with the former method of approach, the dissection has been found of particular advantage in very obese subjects and in cases with extensive old inflammatory change in which hard infiltration of the fat renders difficult dissection through it. It gives a wound free from the relentless impediment of slippery fat that obscures exposure and handicaps every manipulation.

As shown in figure 5, division of the lumbodorsal fascia will have exposed the pararenal fascia, or fascia of Gerota, lying immediately beneath it and only here

and there separated from the lumbar fascia and muscles of the renal fossa by a trifling amount of pararenal fat. Between the two fascias is a clean line of cleavage. This is opened by blunt dissection, the pararenal fascia stripping cleanly away from the lumbar fascia and the muscles of the renal fossa. All fat is thus removed from the surfaces of these structures so that if fixation of the kidney is to be made, a renal fossa of bare muscle surface has been prepared in advance. Upward, the blunt dissection is carried under the diaphragm to an extent necessary to free the upper posterior attachments of the perirenal fat, and downward well below the lower limit of the kidney. The upper ureter will be seen on the posterior surface of the mass of fat covered only by a layer of pararenal fascia. In this

Figure 6

way a large space is opened up behind the whole mass of perirenal fat which remains completely enclosed in an intact investment of Gerota's fascia (fig. 6). The blunt dissection is continued medialward to the vertebral bodies, the pararenal fascia stripping away from the muscles of the fossa without difficulty. This dissection deep in the wound may be facilitated by holding forward with a Deaver retractor the freed fascia with its contained fat and kidney, or they may be lifted up out of the wound as shown in figure 6.

With the kidney and its surrounding mass of fascia enclosed fat thus held medialward, the vertebral bodies may be readily seen and palpated. The renal artery and vein lying immediately under the stripped up Gerota fascia extend medialward toward the great vessels over the vertebral bodies.

As indicated by the dotted line in figure 6, incision is now made through the fascia enclosing the fat. The incision is placed behind and slightly medial to the kidney pelvis. It extends longitudinally from above the level of the upper pole of the kidney, crosses the vascular pedicle, and is continued downward well below the lower pole level. Any desired extent of upper ureter may be exposed by continuing the incision in the fascia downward parallel to the ureter.

The layer of fat at the hilum of the kidney and covering the posterior surface of the renal pelvis is exposed by this incision. As a plaque, it is stripped away from these structures and from the whole posterior surface of the kidney (fig. 7).

Figure 7.

In this process care should be taken to enter exactly the cleavage plane between the lipomatous mass and the structures from which it is to be separated. If nephropexy is contemplated, loosening of the true capsule of the kidney must be avoided. In cases with dense inflammatory infiltration, the usually well defined cleavage plane between fat and kidney capsule may be obliterated. Under such circumstances, if the kidney is to be removed, the true capsule may be incised on the posterior surface of the kidney along its medial concave margin and the organ shelled out of its own true capsule (modified subcapsular nephrectomy). Serious difficulty will be encountered in this process only in cases in which there is extreme inflammatory change.

Stripping of the perirenal fat away from the posterior surface of the kidney is continued to the lateral convex margin and on over the anterior surface (fig. 8). The whole mass of surrounding perirenal fat still attached to the Gerota fascia which enclosed it thus will have been removed from the fossa. Covered by gauze, it may be held medialward out of the way for the rest of the operation. The abdominal viscera, duodenum, pancreas and colon, uncovered by peritoneum posteriorly, overlie the portion of fat anterior to the kidney and are thus retracted forward well out of the way. The intervening layer of fat between them and the kidney protects them.

At the hilum of the kidney and over the vascular pedicle troublesome bleeding will be avoided only by very gentle stripping of the fat. By this process, however, the structures entering the sinus renalis may be completely denuded, permitting a careful and detailed examination of them.

Figure 8.

In figure 9, the structures concerned in this dissection are shown both in their original undisturbed relations (left side) and in the relations established by the dissection (right side).

*Operative Examination and Considerations.*—Even though the most comprehensive kind of preoperative clinical examination has been made and the operation has been undertaken for the particular purpose of fixation of the kidney, the opportunity presented for further visual and tactile examination of the well exposed kidney should not be neglected. Particular attention should be paid to the renal vascular arrangement, the relations and anatomic condition of the upper ureter and the ureteropelvic junction and the degree of muscular irritability exhibited by the latter structure.

Not infrequently nephroptosis produces symptoms only when it exists in combination with some, perhaps insignificant, abnormality of these structures. Of these conditions, which with nephroptosis may be mutually responsible for symp-

toms, the most frequent are anomalies of the renal vascular arrangement. They are found as separate supernumerary arteries and veins entering the sinus renalis below the main vessels. They may have origins from cava and aorta separate from the main vessels or may exist merely as premature branchings of them. In either case the anomalous branches may act as obstructing bands if they are so disposed in their relation to pelvis and ureter as to permit folding of these structures over them incident to descent of the kidney. There is a particular arrangement of such vessels which requires little more than normal kidney mobility in order to make trouble; the anomalous vessel passes in front of the ureter but is inserted into the crevice between the posterior surface of the pelvis and the posterior lip of the sinus renalis. This course of the vessels in front of the ureter, through the crotch of the ureteropelvic junction to their insertion behind the pelvis, will not permit them to slip up over the front of the pelvis on descent of the kidney. Instead, the ureteropelvic junction straddles the vessels which make pressure on it

Figure 9.

with interference to drainage. Painsstaking and careful examination of the vascular arrangement has shown the presence of this situation in a number of cases.

Another factor mutually responsible with anomalous vessels as the cause of symptoms is "horizontal axial rotation of the kidney." This is to be distinguished from ptosis. It may be demonstrated in a comparison of pyelograms made in the recumbent and in the fully erect standing position. On assumption of this position the kidney rotates on its horizontal axis, the upper pole coming forward. This will have been evident in the pyelogram by decrease of the pole to pole dimension and by reduction or closing of the angles between the calyces due to the forward oblique plane which the kidney presents to the ray in its altered position. There need be little or no actual descent. Pitching forward of the upper pole folds the ureter over the anomalous vessel crossing in front of it with resultant interference with drainage. This condition associated with anomalous vessels as found at operation has been demonstrated repeatedly by urography, and the symptoms relieved by appropriate surgical procedures.

The anomalous vessel rarely is found only as a persisting obliterated fibrous cord. Satisfactory explanation for this is found in the morphogenesis of the renal vascularization.

What flimsy structures, "bands" or "adhesions," about the ureter and pelvis are of clinical importance may be difficult to say. The ureter is separated from them in the process of exposure for examination. Definite and well localized investments of inflammatory fat may be found. In conjunction with ptosis these may be important in preventing the ureter from following movements of the kidney, thus causing obstruction at the point of fixation. The ureter must be dissected free from such inflammatory tissue and the latter removed when possible.

There may be extreme irritability of the pelvic and ureteral muscle as evidenced by violent and persistent contraction in response to the stimulation of gentle touch. Spasm of the muscle spreads from the point of stimulation. The ureter becomes reduced to a blanched white cord. In less violent manner the pelvis contracts and may remain so for several minutes. In two cases in which this extreme muscle irritability was observed in conjunction with ptosis, "renal perivascular sympathectomy" was done, together with the kidney fixation. In both instances, relief of painful symptoms was complete. Whether or not sympathectomy contributed to this is impossible to say.

*Procedures Other Than Nephropexy.*—With the exposure here described completed and the careful visual and tactile examination made, the particular operative procedure indicated and required may be undertaken. Whatever this may be—nephrectomy, nephrotomy, pyelotomy, division of vessels, ureterolysis, pelvio-ureteroplasty, nephropexy—it will be greatly facilitated by the exposure which has been obtained.

If nephrectomy is to be made, excellent access to the vascular pedicle is available. The pedicle will have been approached through a clean natural line of cleavage and mobilized almost to its origin at the great vessels. It will be exposed medial to any mass of infiltrated fat which may be present, the latter having been encircled posteriorly by the dissection. In almost every case it has been possible to clamp the vessels doubly, the second clamp being applied crosswise to the first. Spilling of blood into the wound has not been considered a matter of any consequence. Accordingly, the vessels regularly have been divided distal to both clamps and twice ligated. For this purpose a doubled strand of heavy catgut, rendered soft and pliable by thorough soaking, has been used. Stiff and hard gut is assumed to be dangerous. The proximal clamp is slowly released as the first ligature is drawn down, the pedicle being still under control of the distal clamp. A second ligation is made with release of the distal clamp.

Recommendation of this method of exposure for nephrectomy is supported by the fact that in no case in which it has been employed has it been deemed prudent or necessary to forego ligation in favor of leaving a clamp on the pedicle.

*Nephropexy.*—For nephropexy, the technic employed contemplates a positioning of the kidney and ureter in relationship to each other and to surrounding structures that will give no interference to drainage through the ureter or traction on the vascular pedicle. It does not misconceive the temporary function of suture material and recognizes that in the tissues concerned, sutures are merely capable of maintaining for a few days, under little or no tension, certain relationships between structures which may become permanent only by the processes of tissue proliferation and repair. It seeks to approximate intimately and maintain in this relationship the available tissues best suited to these processes with exclusion from their surfaces of contact and desired union tissues and substance which would interfere with the processes. To these ends the whole extent of posterior surface of intact renal capsule, a surface of readily proliferative endothelial cells, is placed in intimate contact with the bare muscles of the renal fossa. Although the approxi-

mation is maintained under virtually no tension, it is sought to insure it undisturbed by a particular method of placing the sutures in the renal capsule that gives them a staunch anchorage of maximal extent. The method not only securely holds the kidney in its new position, but it adequately serves the equally important purpose of positively excluding insinuation of fat between the approximated surfaces.

In figure 10, the method of fixation is illustrated. As already detailed, removal of all fat from the renal fossa and from the kidney itself has been accomplished as an incident in the process of exposure. The muscles of the renal fossa, including a considerable extent of diaphragm, present a clean bare surface. The whole mass

Figure 10.

of perirenal fat is held forward toward the midline, carrying with it the overlying abdominal viscera, and is thus free to gravitate downward without traction on the kidney. The completely mobilized kidney is thoroughly exposed and accessible.

The kidney bridge or elevator of the operating table is now lowered in order to restore the normal relations and configuration in the renal fossa. The kidney is placed well up in the fossa and the obtainable position which best insures against interference with drainage through the ureter or traction on the vascular pedicle is determined. This position of the kidney as a projection to the skin surface is carefully noted or even may be marked on the skin.

The kidney is then brought out into the wound again and the sutures, as shown in figure 10, are placed in its capsule. The material regularly used has been no. 1

or 2 chromic catgut integrally affixed to a long straight atraumatic needle, there being no doubling of the strand as occurs at the eye of the ordinary needle. This is an important detail as tearing of the capsule is most likely to occur when the bent double gut is drawn through in the eye of the ordinary needle. At least four, but preferably five or six, such sutures are placed in the capsule. The ends are left long. Each suture extends under the capsule entirely across the posterior surface of kidney from lateral to medial margin. If the surface is flat the whole distance may be covered in one passage of the needle.

Each end of these sutures is separately brought through the whole thickness of the wall of the renal fossa, emerging on the skin surface of the flank. For this purpose, a long half-curved cutting needle has been used. The ends of some of the upper sutures are passed above the twelfth rib and so have a transpleural course across the angle between diaphragm and thoracic wall. The lung does not extend down into the angle far enough to be caught. In no case have these transpleural sutures produced ill effect.

The predetermined position for the kidney having been carefully noted or marked as a projection on the skin of the flank, it is possible so to place the passage of the suture ends as to bring up the kidney exactly into this position. None of the sutures is tied on the skin until all have been passed. Before tying them the fossa is thoroughly dried. A large piece of gauze, well wet in hot saline solution, packed into the fossa and held in place for a few minutes will control any persistent oozing. Traction on the suture ends which have been brought through the skin draws the kidney up into position, its whole posterior surface coming into intimate contact with the bare muscles of the renal fossa. As shown in the insert, figure 10, each pair of suture ends is tied down on the skin surface over a protecting pad of gauze. The number of sutures, their extent in the capsule, and their close spacing insures the largest possible area of approximation with positive exclusion of all fat, clot and serum.

The pararenal fascia with its mass of attached and overlying viscera is allowed to fall back into position in front of the kidney. It is neither necessary or desirable to suture it in position. If there is much moisture, a small rubber tissue drain may be placed in the wound which is closed in the usual way.

For four or five days after operation, it is felt desirable not to elevate the foot of the bed. A horizontal position or even elevation of the head of the bed is probably preferable during this period as the fixation is perfectly competent to hold the kidney securely in position for a few days, at the same time permitting the unattached lipomatous mass with overlying viscera to gravitate downward. This may be of some importance in avoiding the establishment of relations which would permit traction on the kidney due to subsequent ptosis of these structures. After the fifth or sixth day, there is no confidence that the sutures are competent to hold the kidney in position. To avoid strain on the weak attachments which have formed, it is desirable now to elevate the foot of the bed. This position is maintained until the fourteenth day. A back rest is allowed on the twenty-first day, after which activity gradually may be resumed.

#### SUMMARY

1. The present disfavor in which nephropexy is held results, first, from past employment of the operation for relief of symptoms not caused by abnormal mobility of the kidney and, secondly, from employ-

ment of faulty methods for nephropexy incapable of actually accomplishing fixation of the kidney.

2. An improved method for nephropexy, which has regularly given excellent results in carefully studied cases subjected to rigorous diagnostic criteria, is described.

3. The first part of the dissection employed in the operation for fixation is submitted as an improved method for exposure of the kidney which may be employed in all renal surgical procedures.

# LATERAL STRUCTURAL CURVATURE OF THE SPINE

## TREATMENT BY MEANS OF THE TURNBUCKLE JACKET AND TURNBUCKLE SHELL

A. H. BREWSTER

Lateral curvature of the spine presents itself in two groups: (1) functional curves, and (2) structural curves. The first, I believe to be caused by bad posture because the curve is not present when the patient is recumbent. The second, often called organic or fixed, shows actual change in the normal shape and position of the bodies of the vertebrae, and the curve or curves do not disappear in recumbency. It is the latter group which from the earliest time has been recognized as a deformity of the spine having a tendency to increase. All men who come in contact with structural scoliosis soon learn to appreciate its importance. Experience alone teaches that its end-results are deformities rivaling any others seen in the realm of orthopedic surgery. Experience also teaches its treachery and resistance to all methods of treatment.

The steady progress of many cases of structural scoliosis to the stage of great distortion and unsightliness, in spite of all efforts of correction, makes them an interesting group to study. Fully cognizant of all the mechanical difficulties presenting themselves as a fortification against correction, the following method is described as one which offers a means by which certain groups of persons can be isolated and benefited. Any means of therapy which can help in the slightest degree to stay the progress of the deformity of structural lateral curvature seems justifiable although it may do so in only a small group.

The turnbuckle jacket for correction of structural lateral curvature was first used in November, 1923. In searching the literature, the following references were found: Hanausek<sup>1</sup> described a jacket cut circularly in two sections controlled by two long wooden rods which he used temporarily for twisting laterally curved spines. Hibbs<sup>2</sup> refers to a turnbuckle jacket, but no further description can be found. The use of a turnbuckle in the forcible treatment of Pott's disease is described in numerous articles, particularly by the German authors.

### TECHNIC OF TURNBUCKLE JACKET

*Construction.*—A patient with a right dorsolumbar curve, with the apex of the curve at the twelfth dorsal vertebra, is suspended in a Sayre head sling until his toes are just touching the floor. He holds on to the bars above his head with his hands. This position hyperextends the spine and elevates the scapulae as

1. Hanausek, J.: Contribution au traitement de la scoliosae par les corsets plâtrés, *Rev.d'orthop.*, March, 1922, p. 127-137.

2. Hibbs, R. A.: Scoliosis Treated by Fusion Operation, *J. Bone & Joint Surg.* 6:3 (Jan.) 1924.

well as making them prominent laterally. Both of these points are important in the construction of the jacket. A plaster jacket is then applied from high up in the axillae down over the greater trochanters, taking particular care to mark out the anterior superior spines and inguinal regions. This is immediately removed by a front midline incision and a few more plasters wound around to hold it in shape. A wooden box is then obtained and a hole is made through its center. A steel rod is passed through this hole in the box; the rod in position is perpendicular to the floor. The jacket is so placed on the box that the steel rod passes directly through its center and is then filled with plaster mud and allowed to set. The jacket is removed and the torso is ready for hewing (figs. 1 *A* and *B*).

The steel is placed in a vice and the torso is hewed. The prominence on the torso caused by the elevated scapulae is cut away and about 1 inch is also hewed from the top of the torso posteriorly. The torso is then considered squared (fig. 1 *C*). This hewing is necessary to prevent the finished jacket from being too large at the top. The next step is to mark out the inguinal regions and shave off the abdominal prominence. It is most important not to lower or change the contour of the iliac crest because such a change makes the final jacket very uncomfortable from pressure on these bones, particularly the anterior superior spines (fig. 1 *D*).

With the squaring of the torso finished, as well as the abdominal prominence shaved away and the inguinal regions marked out, correction of the torso is begun. If the curve is a right dorsal, left lumbar curve as shown in figure 1 *B*, the right prominence is shaved with a draw knife as much as it is evident the patient can stand. The left hip is then lowered and the part of the torso at the top, left posterior, is hewed away. This decreases the left concave side of the body making it approach a straight line. (Compare fig. 1 *B*, fig. 1 *C* and fig. 1 *F*.) By the foregoing procedure, it is readily seen that pressure is exerted at points *a*, *b* and *c*, as shown in figure 1 *F*. This is the same principle on which most forcible jackets work—only in a less efficient manner—by representing the place the pads are forced in, *a* and *c* the top and bottom of the jacket. A triangular area about 1 inch deep at the top and tapering off at the apex, is then cut out. This is done so the jacket will fit skin-tight between the scapulae, and also prevents the clothes being pushed out in the back—a point patients appreciate (fig. 1 *F*).

After the torso is cut as described, a new plaster jacket is put on and immediately cut off by a front line incision (figs. 2 *A* and *B*). This jacket ought not to be more than three-eighths of an inch thick and should be the same thickness throughout. Seven plasters will, as a rule, give just about the right thickness.

*Application.*—After the jacket is dry, about 4 or 5 inches are cut off at the top in order that the patient may be comfortable with the arms hanging at the sides. It is necessary to remove enough at the top so that the circulation will not be impaired. At the bottom, the jacket is cut off about 1 inch below the anterior superior spines tapering downward posteriorly. This allows the patient to sit comfortably (fig. 2 *C* and *D*).

The jacket is put on; the patient reclines on a table and an assistant holds the patient's arms while the jacket is pulled well down. The temporary straps are tightened while the patient is on the table. If the jacket fits correctly, the patient is unable by putting his hands on his hips and pushing his body up to get out of the jacket (fig. 3 *A*, *B*, *C* and *D*). The jacket is worn for a day or so to be sure that it exerts pressure over the rotation being attacked. This is shown by a slight redness of the skin. *The jacket must be comfortable.*

Fig. 1.—*A*, front view of uncut torso showing steel rod through center; *B*, back view of uncut torso showing prominence of right dorsolumbar curve; *C*, same torso as in *B* after it has been squared; *D*, front view of torso after abdominal prominence has been shaved away and inguinal regions marked out; *E*, front of finished torso; *F*, back of finished torso; *a*, *b*, and *c* represent the points of pressure described.

Fig. 2—*A*, front view of finished jacket; *B*, back view of finished jacket; *C*, front view of jacket after it has been cut at top and bottom; *D*, back view of jacket after it has been cut at top and bottom.

Fig. 3.—*A*, first fitting of jacket; ready to be worn for trial; *B*, back view of jacket; ready to be worn for trial; *C* and *D*, front and back views of jacket showing patient pushing up demonstrating inability to push out of jacket.

The general principle of the construction and application of the jacket up to this point was described by R. W. Lovett and J. W. Sever.<sup>3</sup>

*Method of Splitting and Applying a Turnbuckle Jacket.*—When a patient has a right dorsolumbar curve with the apex of the curve at the twelfth dorsal vertebra a string is tied around him at the level of this vertebra. The jacket made from the corrected torso, which gives pressure at the desired points and has proved to be comfortable, is applied. At a point in front at the level of the string, the jacket is marked. This point is higher than the level of the twelfth dorsal vertebra because in putting on the jacket in the recumbent position the skin is pulled up more than the spine is extended. A line is then drawn around the jacket about one-half inch below the front mark. A cross is put in the left midaxillary line at the level of the circular mark to indicate where the hinge is to be placed. On the right side in the midaxillary line, at the top and bottom, crosses are made indicating the position of the boxings for the removable turnbuckle. Lines are drawn around the jacket indicating where it is to be steeled. In front, marks are made indicating where the boxes for the top and bottom stays are to be placed. The jacket is then sent to the appliance shop, and the hinge, boxings and steels are put on before the circular incision separating the jacket into two parts is made. This is necessary in order to keep the exact relations of the two parts. The position of the front and back locking device has to be determined by the mechanic and adjusted so it will work easily when the jacket is turned up or down. The buckles and straps for fastening are routine and always occupy the same position. Figure 4 and 5 show the finished jacket from the front, from the back, in every position, with or without the turnbuckle.

*Construction of Turnbuckle Shell for Recumbency.*—A patient with a left dorsolumbar curve centering at the twelfth dorsal vertebra, is placed on an ordinary Bradford frame, face down and in a straight position. Straps are run lengthwise of the frame to hold the patient. A plaster shell is applied including the head and all the body down to the middle of the lower legs. Care is taken to mold the shell to fit the body and to shape it well up over the chest and hips anteriorly.

While the patient is still in the shell, the place for the hinge is marked. The exact position for the hinge is obtained by tying a string around the body at the desired level, and a mark is made to indicate the position. This is done before the patient is placed on the frame. The shell is removed and cut evenly around the edges and trimmed off at the bottom just at the bend of the knees. The mechanic then applies the hinge where indicated by the mark and mounts the shell on a plank by means of steel supports. A second hinge is placed on the plank so that its center of action is the same as that of the one on the shell, but at a lower level, like the hinge of a door. The shell and board are then cut at the same level. The locking device is placed on the opposite side of the board from its hinge and is simply a slotted steel rod working on a small steel upright which is threaded to take a thumb screw. The shell is well padded and covered with stockinet. The construction of the shell, excepting the hinges and split board, was described by R. Plato Schwartz<sup>4</sup> for treatment of tuberculosis of the spine.

4. Schwartz, R. Plato: Mechanics of a New Plaster Shell in Pott's Disease in Children, with Lateral X-ray Control, *J. Bone & Joint Surg.* 4:789 (Oct.) 1922 (fig. 6 A and B).

*Mechanical Principles of Turnbuckle and Shell.*—The mechanical principles of the turnbuckle jacket and shell are exactly the same. The simplicity of their mechanics is their virtue.

A laterally curved spine represents one or more arcs. The problem is to straighten the spine, and to do so one must employ a method which entails no harm to the patient and correctly obeys mechanical laws. To break an arc, three forces are necessary: (1) a resisting force on the convex side of the keystone at its center; (2-3) an active force at each end exerting pressure on the concave side. Such forces if strong enough will snap the arc. To straighten an arc three forces are also needed but differently employed: (1) a resisting force evenly distributed over all the convex side of the keystone; (2-3) an evenly distributed force working on the entire concave side of each limb of the arc. The turnbuckle jacket and shell furnish the forces used to straighten an arc. Another mechanical principle of the turnbuckle jacket and shell is that they are eccentric. The hinge on either does not correspond to the center of motion in the spine and when they are opened they are elongated, which produces a distraction of the spine above and below the part opposite the hinge.

#### CHOICE OF PATIENTS FOR TREATMENT WITH TURNBUCKLE JACKET AND SHELL

The turnbuckle jacket is of little avail in old ankylosed cases with marked rotation. It is not efficient in a curve the apex of which is above the eighth dorsal vertebra. The turnbuckle shell is effective in cases of infants with congenital scoliosis who are too small to walk, and for curves the apexes of which are higher than the eighth dorsal vertebra.

The fact must not be lost sight of that the gymnasium with trained physiotherapists is a valuable asset in any method of forcible correction of lateral structural curvature of the spine. The back and abdominal muscles must be kept in good tone by regular visits to the gymnasium for exercises and massage.

At first the patient wears the jacket for a week in the turned down position (fig. 4 *A* and *B*). Then it is turned up just as far as it is comfortably borne; it is locked in this position and worn night and day. The patient should never bear weight without the jacket on. Some patients can have the jacket turned up almost to the maximum on the first day, but this is probably a little dangerous. Once a week it should be turned up one or two notches until the desired correlation is obtained.

If the turnbuckle is correctly made, the patients do not object to the pressure it exerts, and in all the patients treated a pressure sore has never been experienced.

Experience in the use of this method of treatment of structural scoliosis permits the following conclusions:

1. It effects mobilization of the spine by stretching all the tissues on the concave side and allows the stretched tissues on the convex side to regain some of their lost tone.

Fig 4—*A* and *B*, front and back views of turnbuckle jacket on patient, closed, turnbuckle removed, *C* and *D*, front and back views of turnbuckle jacket on patient, closed, turnbuckle in position

Fig. 5—*A* and *B*, front and back views of turnbuckle jacket on patient, opened, turnbuckle in position; *C* and *D*, front and back views of turnbuckle jacket on patient, opened, turnbuckle removed. This is as jacket is worn.

2. The force applied spreads the ends of the arc and does not disregard the mechanical law that the keystone is the strongest part of the arc.

3. It permits gradual correction.

4. It will produce an immediate correction of certain moderate curves.

5. It tends to decrease rotation, as seen clinically and in the roentgenograms.

6. It secures the means of obtaining an adjustable overcorrective retention jacket.

Fig. 6.—*A*, complete turnbuckle shell, padded and covered ready for use; *B*, complete turnbuckle shell, open, showing position of hinge, plank, and the locking device, marked *m*.

7. It increases the height.

8. It is not uncomfortable and is not noticeable when the patient is dressed.

Certain other conclusions will be drawn after the study of the cases is finished.

#### RESULTS OF TREATMENT

This article is based on a study of 100 cases of structural lateral curvature of the spine. An effort is made to show just how efficient the turnbuckle jacket and turnbuckle shell are, and the types of structural lateral curves benefited as well as those not benefited.

It is impossible to present in such a publication all the photographs and roentgenograms in the 100 cases. Therefore photographs and roentgenograms made in cases 38, 39 and 43 are used to demonstrate the method and the results obtained.

Figures 7 and 8 are from case 42; figures 9 and 10, from case 39, and figures 11 and 12, from case 38. These photographs are taken in the Osgood frame by the same man, who always used the same camera in

Fig. 7 (case 43).—Patient, aged 9 years; turnbuckle first applied, on June 24, 1924; degree of correction obtained, fair. *A, B and C* were taken on April 24, 1924; *D, E and F* were taken in December, 1925.

the same room. The roentgenograms in case 70, figure 13, are presented to show the results obtained in a dorsolumbar curve, which, of course, is the ideal curve in which to obtain the best correction.

The table is continuous, but for the sake of comparison, all right curves were collected in their respective groups and numbered in sequence; the left curves follow in the same manner.

There are sixty-six patients with right curves of various kinds, seven of whom were not treated with the turnbuckle jacket; this leaves fifty-nine who were treated by either the jacket or shell, or both. Twenty-three, or 38.98 per cent, of the fifty-nine patients had single curves; thirty-four, or 57.62 per cent, had double curves, and two, 3.4 per cent, had triple curves. It is interesting to compare these three groups of patients. In all of those with the single curves, some correction was obtained; in eleven, or 47.82 per cent, the results were excellent; in

Fig. 8 (case 43) —Taken on Oct 18, 1924

five, or 21.73 per cent, they were good; in five others, fair, and in two, or 8.69 per cent, poor. In the patients with double curves, the results were excellent in four, or 11.7 per cent; in fourteen, or 41.17 per cent, they were good; in ten, or 29.41 per cent, fair; in four, or 11.7 per cent, poor, and in two, or 5.88 per cent, no correction was obtained. In the two patients with triple curves, no correction resulted.

There are thirty-four patients with left curves of all types, eleven of whom were not treated by the turnbuckle jacket or shell; the remaining twenty-three were treated by either the shell or the jacket, or both. Eight of these, or 34.78 per cent, had single curves; eight had double

curves, and seven, or 30.43 per cent, had triple curves. In the patients with single curves who were treated, some correction was obtained in all except one; in three, or 37.5 per cent, the results were excellent; in two or 25 per cent, good; in one or 12.5 per cent, fair, and in another patient, poor, while one showed no correction. In the patients with double curves, the results in three, or 37.5 per cent, were excellent; in

Fig. 9 (case 39).—Patient, aged 7 years; first visit in March, 1924; application of first turnbuckle jacket on Aug. 23, 1924 for right curve; jacket worn continuously for over one year. *A* and *B* were taken on May 23, 1924; *C* and *D* were taken in October, 1924.

two, or 25 per cent, fair; in three, or 37.5 per cent, no correction was obtained. In the patients with triple curves, the results in one, or 14.28 per cent, were fair; in another, poor, and in the remaining five, or 71.42 per cent, no correction was obtained. Good or excellent results were not obtained in any of the cases.

\* Key to table: RL, right lumbar; RDL, right dorsolumbar; RD-LL, right dorsal, left lumbar; RDL-LL, right dorsolumbar, left lumbar; RD-LDL, right dorsal, left dorsolumbar; RCD-LDL, right cervicodorsal, left dorsolumbar; RCD-LD-RDL, right cervicodorsal, left dorsal, right dorsolumbar; RCD-LDL-RL, right cervicodorsal, left dorsolumbar, right lumbar. The lettering for the left curves follows the same principle and need not be outlined.

Etiology: I, infantile paralysis; U, unknown; R, rickets, and C, congenital.

All degrees of correction are determined by the last roentgenogram taken in the turnbuckle jacket. They are classified as follows: excellent, perfect or practically straight spine; good, definite correction; fair, correction easily seen in comparing roentgenograms taken in and out of jacket; poor, slight demonstrable correction; N C, no correction, and N T, turnbuckle not used.

Considering the entire series, eighty-two patients were treated by the turnbuckle jacket or shell, or both. Of this number thirty-one, or 37.86 per cent, had single curves; forty-two, or 51.2 per cent, had double curves, and nine, or 10.95 per cent, had triple curves. In the patients with single curves, excellent results were obtained in fourteen, or 17.07 per cent; good results in seven, or 8.55 per cent; fair in six, or 7.32 per cent; poor in three, or 3.73 per cent, and no correction in one, or 1.21 per cent. In the patients with double curves, excellent results were obtained in seven, or 8.55 per cent; good results in sixteen, or 19.5 per cent; fair in ten, or 12.19 per cent; poor in four, or 4.87 per cent, and no correction in five, or 6.09 per cent. In those with triple curves, no excellent or good results were obtained. In one, or 1.21 per cent, poor results were obtained; in one, fair, and no correction was shown in seven, or 8.53 per cent.

Fig. 10 (case 39).—*A* was taken on Feb 17, 1923; *B*, on Oct. 18, 1924; *C*, on Feb. 14, 1925, and *D*, on Oct. 24, 1925.

Fig. 11 (case 38).—Patient, aged 14 years; first turnbuckle jacket applied on Aug. 9, 1924; jacket worn faithfully. *A, B* and *C* were taken on May 3, 1924; *D, E* and *F* were taken in November, 1925.

Condensing the foregoing figures it is found that twenty-one patients, or 25.62 per cent, showed excellent results; the results in twenty-three, or 28.05 per cent, were good; in seventeen, or 20.72 per cent, fair; in eight, or 9.81 per cent, poor, and in thirteen, or 15.83 per cent, there was no correction.

These figures and percentages make the following conclusions justifiable:

1. No type of curve which is of long duration, with marked rotation and in which ankylosis has occurred, can be affected in the least by the method of treatment described.

Fig 12 (case 38) —Taken on Oct. 18, 1924

2. Single curves, either right or left, the apexes of which are below the eighth dorsal vertebra, are the ones most favorable to correction by this method.

3. Double curves, either right or left, with the apex of the upper curve not higher than the eighth dorsal vertebra, can be helped, but are not nearly so amenable to treatment as single curves.

4. Triple curves do not lend themselves to treatment at all.

5. The foregoing conclusions follow the law of common sense that a single curve in a rod is easier straightened than a series of curves, the difficulty increasing with the number of curves.

Fig. 13 (case 70).—Patient, aged 18 years; first visit, on Jan. 14, 1924. *A*, taken on Jan. 15, 1924; *B*, on Feb. 16, 1925; *C*, on Sept. 8, 1925. Turnbuckle jacket first applied on Jan. 30, 1924.

# INCREASED INTRACRANIAL PRESSURE ASSOCIATED WITH SYPHILIS

CHARLES EDWARD LOCKE, JR.

For many years it has been a recognized fact that headache and choking of the optic disks may occur in conjunction with a syphilitic infection. In 1893, Uhthoff<sup>1</sup> stated that choked disk was a common occurrence in cerebral syphilis and that, except for cerebral tumor, cerebral syphilis was the most frequent cause of this condition. Two years later, a similar conclusion was reached by Rochon-Duvigneaud.<sup>2</sup> Among 2,636 patients in the early stages of syphilis examined by Fehr<sup>3</sup> between 1910 and 1912, he found papilledema in about 0.5 per cent. Soon after the advent of arsphenamine several authors reported cases in which this drug was held to be responsible for the development of papilledema. Fehr, however, showed by his statistics that such changes of the optic nerve occur far more frequently in untreated patients than in those treated by arsphenamine. A few years later (1916), Wilder<sup>4</sup> concluded that in many cases of cerebral syphilis a choked disk is seen which cannot be distinguished clinically from that seen in cases of intracranial neoplasm. De Schweinitz<sup>5</sup> (1924) concurred with Uhthoff's statement concerning the frequent occurrence of choked disk in syphilis, and Fuchs<sup>6</sup> (1925) also recognized its existence, stating that it is most apt to occur within the first three years after the primary infection. Bordley<sup>7</sup> (1925), who with Dr. Cushing several years ago contributed largely to the establishment of the mechanical theory of choked disk, made the statement that "syphilis is probably the most frequent of all 'medical causes' in the production of choked disc."

Among the patients examined in the neurosurgical division of the Cleveland Clinic during the past four years, there were 390 cases in

which either a positive or a presumptive diagnosis of tumor of the brain was made. In this series there were eleven cases in which the Bordet-Wassermann reaction was positive, and six of the eleven patients had signs and symptoms of increased intracranial pressure. It was thought at first that these were cases of tumor of the brain, but further study and the clinical course indicated that undoubtedly the increased intracranial pressure in these cases was associated with cerebral syphilis. The information gained from the study of these six cases has furnished the material for the present report.

#### REPORT OF CASES

*CASE 1.—History of primary syphilitic infection; signs of intracranial pressure developing one year after the infection in spite of antisiphilitic treatment; decompression with continued antisiphilitic treatment; relief of intracranial pressure; recovery.*

*History.*—A single man, aged 22, a college student, was referred to the Cleveland Clinic on May 18, 1925, complaining of severe headache, vomiting and double vision.

In August, 1924, the patient had a genital chancre followed by a secondary skin lesion. The Bordet-Wassermann reaction of the blood was positive, and the patient received nine injections of neoarsphenamine followed by the administration of mercury and iodides. About January, 1925, or five months after the primary lesion, he commenced to have severe frontal headaches. In February, 1925, severe suboccipital headaches developed, associated with vomiting; double vision was noted, and the patient became delirious, but there was no elevation in temperature. Numbness was experienced on both sides of the lips and in both hands. A lumbar puncture was made at this time, the spinal fluid showing a negative Bordet-Wassermann reaction. The patient was then confined to bed for ten days following which there was relief of headache and of other symptoms. On March 27, 1925, he again became delirious, had severe suboccipital headache, vomiting and diplopia. He remained in bed until May 9.

*Physical Examination.*—Physical examination revealed a well developed and well nourished young man. The temperature was 98.6 F.; the pulse rate, 75, and the blood pressure, 110 systolic and 70 diastolic. The patient was found to be normal except for a scar on the penis. There was no adenopathy.

*Neurologic Examination.*—The head was normal in size and shape, with no areas of tenderness and no exostoses; the percussion note was normal. Examination of the cranial nerves revealed: first nerve, subjectively and objectively normal; second nerve, no visual field changes, marked choking of the disks with edema and hemorrhages, some new tissue formation, elevation of 4 diopters in the right eye and 3 diopters in the left eye, vision in the right eye 6/12, and in the left 6/15; third, fourth and sixth nerves, horizontal diplopia, slight weakness of the external rectus of the right eye, fine lateral nystagmus to the left; fifth nerve, normal; seventh nerve, marked asymmetry of the lower part of the face with weakness of the right side (fig. 1, A) and symmetry of the upper part of the face; eighth nerve, tinnitus of the right ear, hearing normal; ninth, tenth, eleventh and twelfth nerves normal. Examination of the motor nerves revealed: no paresis, no atrophy or hypertrophy and no abnormal tonicity. Sensory examination showed: pain, touch, temperature and vibratory sensations normal. Examination of the reflexes revealed: biceps, triceps and radials slightly hyperactive on the left; both patellars,

hypo-active; other deep and superficial reflexes, normal. There were no pathologic reflexes. Vasomotor action was normal. Cerebral examination revealed: frontal and temporal lobes normal; precentral lobe, weakness of the right lower part of the face; postcentral and occipital lobes, normal. Cerebellar examination showed: slight hypermetria to "finger to nose" and "heel to knee" tests on the left side. There was lateral nystagmus, and slight static ataxia of the left arm.

*Laboratory Examinations.*—The urine was normal, also the blood counts. The Bordet-Wassermann reaction of the blood was 4-4-4; the Kahn test, +++. A roentgenogram of the skull was normal. The visual fields were normal

A

B

Fig. 1. (Case 1).—*A*, the patient a few days after right subtemporal decompression, showing weakness of lower portion of right face; *B*, three months after operation.

Lumbar puncture was omitted because of the marked signs of intracranial pressure. Ventricle fluid taken at the time of operation showed clear fluid, 24 cells, and a marked trace of globulin; the Bordet-Wassermann reaction was 4-4-4 and the colloidal gold reaction, 5555544311.

*Diagnosis.*—A diagnosis was made of cerebral syphilis with associated increased intracranial pressure.

In view of the fact that after nine injections of neoarsphenamine the patient still had high chocking of the disks with beginning new tissue formation, a decompression seemed necessary to prevent further loss of vision.

*Operation.*—On May 22, 1925, with the patient under local anesthesia, a subtemporal decompression revealed increased intracranial pressure and a moderate dilatation of the right lateral ventricle.

*Postoperative Course.*—Following operation, the choking of the disks rapidly receded and there was bulging of the decompressed area. Strenuous antisyphilitic treatment was continued. The headache, vomiting, facial weakness, nystagmus, hypermetria and delirium were relieved. Vision in both eyes was 6/6 (fig. 1, B). One year later, the Bordet-Wassermann reaction of the blood was 0-4-0.

*Comment.*—High choked disks, headaches and vomiting developed in spite of antisyphilitic treatment. Following subtemporal decompression, with continued antisyphilitic treatment, the choking of the disks disappeared rapidly and the patient was completely relieved of his neurologic symptoms.

*CASE 2.*—*History of genital chancre; ten months later, in spite of extensive antisyphilitic treatment, symptoms of intracranial pressure; decompression and continued antisyphilitic therapy gave relief; recovery.*

*History.*—A married man, aged 46, was referred to the Cleveland Clinic on Oct. 18, 1926, complaining of severe headache, blurred and double vision, and impairment of memory.

In January, 1926, the patient had a chancre and the diagnosis of syphilis was made. The Bordet-Wassermann reaction of the blood was positive, and the patient received extensive intravenous antisyphilitic therapy. In August, 1926, he commenced to have severe bitemporal and occipital headaches, also transient attacks of numbness of the left side of the face and tongue. The headaches continued, becoming more severe. About Sept. 15, 1926, he began to experience disturbance in memory and he slept excessively. He had difficulty in understanding what was said to him and there was some unsteadiness of gait. Since about October 1, he had noted horizontal diplopia.

*Physical Examination.*—Physical examination revealed an unusually well developed and well nourished adult. The temperature was 97.6 F.; the pulse rate, 80, and the blood pressure, 120 systolic and 80 diastolic. The observations made on physical examination showed the patient to be essentially normal.

*Neurologic Examination.*—Examination of the cranial nerves revealed: first nerve, slight impairment on the left side; second nerve, vision in the right eye 6/30, in the left eye 6/60, moderate general contraction of form and color in the visual fields, fundi showed marked choking with well marked edema and numerous hemorrhages, elevation of 3 diopters; third, fourth and sixth nerves, normal except for horizontal diplopia with no demonstrable extra-ocular palsies; fifth nerve subjective history of transient paresthesia of the left side of the face and tongue but objective examination negative; seventh nerve, weakness of the lower part of the face on the right side with the upper facial muscles intact; eighth nerve, moderate impairment of hearing (tuning fork heard only on close proximation); ninth, tenth, eleventh and twelfth nerves, normal. Examination of the motor nerves revealed: slightly ataxic gait, no paresis or paralysis, no atrophy or abnormal tonicity. Sensory examination showed: touch, pain, temperature and vibratory sensations, normal throughout. The reflexes were normal except for hyperactive biceps on the left and absent patellar on the right. The superficial reflexes were normal and there were no pathologic reflexes. Cerebral examination revealed: frontal lobe, marked impairment in memory, moderate tremor of the right hand, and slight anosmia

on the left; temporal lobe, partial anomia and impairment in perception of speech (could not name *safety-pin* or *eyedropper*, but explained their use); precentral, postparietal and occipital lobes, normal. Cerebellar examination showed: moderate dizziness and slightly positive Romberg sign, slight hypermetria to "finger to nose" and "heel to knee" test, on the right and left sides; moderate staggering gait to the right and left.

*Laboratory Examination.*—The urine was normal except for a few pus cells; the blood counts were normal. The Bordet-Wassermann reaction of the blood was 4-4-4; the Kahn test, ++++. Roentgenograms of the skull were normal. The visual fields showed slight general constriction for form and color. Spinal puncture was not made because of signs of increased intracranial pressure.

Fig. 2 (case 2).—Five weeks after right subtemporal decompression. Note the moderate bulging of the decompressed area, which two weeks earlier had been much more marked.

*Diagnosis.*—A diagnosis was made of cerebral syphilis with associated increased intracranial pressure.

Because the patient was suffering from intense headache and because vision was steadily diminishing, it was decided to perform a decompression operation.

*Operation.*—On Oct. 23, 1926, with the patient under ether anesthesia, a right subtemporal decompression revealed markedly increased intracranial pressure with an abundance of subarachnoid fluid.

*Postoperative Course.*—Signs of intracranial pressure rapidly subsided and choking of the disks disappeared. Vision returned in the course of a few weeks to 6/6 in both eyes. The anomia and impairment of perception were relieved. The memory returned to normal. The decompressed area bulged markedly for several weeks after operation and then became level with the temporal bone. Extensive antisyphilitic treatment was continued (fig. 2).

*Comment.*—There was a definite history of chancre. Ten months later, severe signs of intracranial pressure with impairment of vision developed in spite of antisyphilitic treatment. Decompression relieved signs of intracranial pressure.

*CASE 3.—History of genital chancre; two years later, signs of increased intracranial pressure notwithstanding antisyphilitic treatment; decompression and continued treatment; recovery.*

*History.*—A single man, aged 22, a pottery worker, was referred to the Cleveland Clinic on March 29, 1927, complaining of severe headache, vomiting, double vision and staggering gait.

In March, 1925, the patient had a chancre of the penis lasting two weeks. His local physician found a positive Bordet-Wassermann reaction and administered sixteen injections of neoarsphenamine. No further symptoms appeared until about February, 1927, when he commenced to have severe left parietal and suboccipital headaches. One week later, the headaches were associated with strenuous vomiting. About March 1, the patient commenced to have vertigo and he noticed considerable staggering in walking. Two weeks later, double vision was noted and during the next week, prior to admission, there had been transient amblyopia. Also during the last week mild delirium had been associated with the severe headaches. On three occasions he had noted weakness of the right arm lasting for about an hour at a time.

*Physical Examination.*—Physical examination revealed a fairly well developed and well nourished boy, apparently sick. The temperature was 98.6 F.; the pulse rate, 76 and the blood pressure, 85 systolic and 54 diastolic. The observations made on physical examination showed the patient to be essentially normal.

*Neurologic Examination.*—The head was normal in size and shape; the percussion note was normal; there was tenderness to deep pressure in the suboccipital region. Examination of the cranial nerves revealed: first nerve, normal; second nerve, vision 6/6 in both eyes, visual fields normal, marked bilateral choking of the disks, with edema and hemorrhages, elevation of 4 diopters in both eyes; third, fourth and sixth nerves, history of turning-in of the left eye and diplopia; pupillary reaction normal, no ptosis or exophthalmos, irregular lateral nystagmus, more marked to the left; fifth and seventh nerves, normal; eighth nerve, hearing normal, history of vertigo and irregular lateral nystagmus; ninth, tenth, eleventh and twelfth nerves, normal. Examination of the motor nerves revealed: unsteady gait, no paralysis or paresis, no atrophy or abnormal tonicities. Sensory examination showed normal pain, touch, temperature and vibratory sensations. The deep reflexes were all hyperactive; the superficial reflexes normal, and no pathologic reflexes were noted. Vasomotor action was normal. Cerebral examination revealed: frontal lobe, no impairment of memory, no loss of orientation, no change in habits, transient delirium for the past week, and no motor aphasia; temporal lobe, incomplete anomia (could not name objects such as blanket, hinge and electric wire, but named more simple objects such as glass, cup, hand), no characteristic hemianopsia, no hallucinations of smell; precentral lobe, normal; postcentral lobe, transient paresis of the right arm; postparietal and occipital lobes, normal. Cerebellar examination revealed: suboccipital tenderness, headaches, dizziness and associated vomiting, unsteadiness in walking, deviation of gait to right and left, hypermetria to "heel to knee" test on the left side, adiadochocinesia on the right and left side.

*Laboratory Examination.*—The urine was normal except for an occasional pus cell and trace of mucus. The blood counts were normal. The Bordet-

Wassermann reaction of the blood was 4-4-4; the Kahn test, +++. Spinal puncture was not done on account of choking of disks. The visual fields were normal as to form and color. A roentgenogram of the skull was normal.

*Diagnosis.*—A diagnosis was made of cerebral syphilis with increased intracranial pressure.

In view of the fact that the patient had had sixteen injections of arsphenamine and that the high choking of the disks continued, it seemed wise to make a subtemporal decompression to prevent visual impairment.

*Operation.*—On April 2, 1927, with the patient under local anesthesia, a right subtemporal decompression exhibited a markedly increased intracranial pressure with flattening of the cerebral convolutions. There was an abundance of subdural fluid.

Fig. 3 (case 3).—Six months after right subtemporal decompression. The operative scar was invisible at this time and the decompression was no longer prominent.

*Postoperative Course.*—The patient made an uneventful recovery. The headaches and choking of the disks rapidly subsided, and the diplopia, nystagmus, ataxia and speech changes all disappeared. Strenuous antisyphilitic treatment was continued, and on Sept. 20, 1927, the Bordet-Wassermann reaction of the blood was negative. Treatment was still continued (fig. 3).

*CASE 4.*—A young woman, with congenital syphilis, had received extensive antisyphilitic treatment throughout life; following the birth of a child signs of intracranial pressure and convulsions developed; decompression and further antisyphilitic treatment; recovery.

*History.*—A married woman, aged 22, a housewife, was referred to me on May 26, 1927, with the complaint of headache, vomiting and convulsions.

The patient's father had a chancre several months before the patient's birth. When the patient was 4 months of age, she had snuffles and a rash. At the age of 11 months a diagnosis of congenital syphilis was made and treatment was commenced, which had been continued part of each year up to the time of examination. Several Bordet-Wassermann tests had given positive reactions. Six months before the examination, the patient gave birth to a child. Before birth, there was one mild convulsion. About three months later the patient commenced to have very severe generalized headaches, associated with vomiting, dizziness and staggering. About seven weeks before the examination she had another severe convulsion, and following this, there was weakness of the right arm. Shortly afterward, she had two more convulsions, and following the first of these, there was transient paralysis of the left arm, while following the second there was impairment of speech. There had been transient ocular palsies. For three weeks the right ear had been discharging and the patient had had a septic fever, the maximum temperature during this time being 104 F.

*Physical Examination.*—Physical examination revealed a well developed and well nourished young woman, lying in bed, apparently in severe pain. The temperature was 98.9 F.; the pulse rate, 90, and the blood pressure, 110 systolic and 80 diastolic. Except for tenderness over the right mastoid, a discharge from the right ear, and enlargement of the axillary and inguinal lymph nodes, the patient was found to be normal.

*Neurologic Examination.*—The head was normal in size and shape and the percussion note was normal. Examination of the cranial nerves revealed: first nerve, normal; second nerve, transient blurring of vision, visual acuity 6/7.5 in both eyes, no constriction or hemianopsia in the visual fields, choked disk with edema and hemorrhage in both eyes, elevation of 3 diopters; third, fourth, fifth, sixth and seventh nerves, normal; eighth nerve diminished acuity in the right ear, bone conduction lateralized to the right (discharging ear, right); ninth, tenth, eleventh and twelfth nerves, normal. Examination of the motor nerves revealed: gait normal, no paresis or paralysis, no atrophy, no abnormal tonicities. Sensory examination revealed normal pain, touch, temperature and vibratory sensations. The deep reflexes were hyperactive on the right side; the superficial reflexes were negative; atypical Babinski sign was noted on the right. Vasomotor action was normal. Cerebral examination revealed: frontal lobe, moderate impairment of memory for one month with transient loss of orientation; two months before, incontinence of urine for several weeks and marked difficulty in speech following last convulsion; temporal lobe, sensory aphasia with impairment of perception of speech after last convulsion, no characteristic field changes, no uncinate syndrome, no visual hallucinations; precentral lobe, generalized convulsions following one headache, weakness of the right arm; postcentral, postparietal and occipital lobes, normal. Cerebellar examination revealed: suboccipital headache, dizziness and associated vomiting, slight Romberg sign, slight deviation of gait, hypermetria to "finger to nose" and "heel to knee" tests, bilateral adiadochocinesia, anomia, and irregular nystagmus.

*Laboratory Examination.*—The urine showed a trace of albumin and occasional pus cells, otherwise it was normal. The blood count revealed: red cells, 4,440,000; white cells, 8,400; hemoglobin, 75 per cent. The Bordet-Wassermann reaction of the blood was negative (recent series of arsphenamine injections). A roentgenogram of skull showed a diseased mastoid on the right side; otherwise the skull was normal. There was no constriction or hemianopsia in the visual fields.

*Diagnoses.*—Diagnoses were made of cerebral syphilis with increased intracranial pressure, mastoiditis and abscess of the brain (?).

*Operation.*—On May 28, 1927, right mastoidectomy was performed by Dr. McCall. Pus and necrotic material were found in the mastoid cells. Necrotic material from the mastoid showed *Streptococcus hemolyticus*.

*Postoperative Course.*—The septic temperature continued and five days later a blood culture showed *Streptococcus hemolyticus*. The headaches became more intense and the choking of the disks gradually increased to 5 diopters, in spite of antisyphilitic therapy. For this reason it seemed necessary to perform a subtemporal decompression.

*Operation.*—On June 13, 1927, burr-hole openings were made in the temporal, parietal and occipital regions, and cerebral punctures revealed no evidence of pus. With the patient under ether anesthesia, a right subtemporal decompression was then made and the brain was found to be under markedly increased pressure. The ventricle was not dilated.

*Postoperative Course.*—The headaches immediately disappeared and the choking of the disks rapidly subsided. One month later, the vision was 6/6 in the right eye and in the left 6/10. Convulsions ceased, ataxia and the septic temperature disappeared. Intensive antisyphilitic treatment was continued.

*CASE 5.*—*History of primary syphilitic infection; nine years later there developed symptoms and signs of a high degree of intracranial pressure which were not influenced by antisyphilitic treatment; subtemporal decompression combined with antisyphilitic treatment relieved the intracranial pressure.*

*History.*—A married man, aged 32, was referred to me on Dec. 19, 1927, with the complaint of severe headaches, attacks of jerking of the left arm and blurring of vision.

Nine years before (1918), he had had a primary syphilitic infection, and a positive Bordet-Wassermann reaction of the blood had been found. He received intensive treatment for the next year, and then had no treatment until a few months prior to examination. During the past six months the patient had had eleven intravenous injections. For the past year and a half he had complained of frequent momentary attacks in which he experienced a silver flash of light in front of both eyes, transient vertigo and nausea associated with profuse diaphoresis. Usually these attacks occurred several times each day. Two months previously the patient had commenced to have severe and almost constant right frontal and occipital headaches. During this time he had also had several short intervals of blurring of vision. There had been two attacks of jerking of the left arm lasting about one minute without loss of consciousness. No history of sinus infection or any other infection about the head could be elicited.

*Physical Examination.*—Physical examination revealed an unusually well developed and well nourished man; 5 foot, 9 inches in height (175.3 cm.), weight 201 pounds (94.8 Kg.). The temperature was 98.6 F.; the pulse rate, 80, and the blood pressure, 120 systolic and 80 diastolic. The observation made on physical examination showed the patient to be essentially normal except for a slight enlargement of the heart. There were no abnormal heart sounds or murmurs.

*Neurologic Examination.*—The head was normal in size and shape; the percussion note was normal, and there were no scars or exostoses. Examination of the cranial nerves revealed: first nerve, olfactory sense slightly diminished on the right and left; second nerve, transient blurring of vision with history of attacks in which the patient saw a silver flash, vision 6/10 in the right eye and in the left 6/7, perimetric fields normal except for marked enlargement of the blind

Figure 4

Fig. 4 (case 5).—Drawing from a sketch made at operation illustrating the extensive leptomeningitis. The markedly thickened arachnoid formed a whitish, opaque, irregular line on either side of the cortical vessels in the cerebral sulci.

Figure 5

Fig. 5 (case 6).—Drawing from a sketch made at operation illustrating the leptomeningitis found at operation. Note the whitish, opaque multi-angular areas in the cerebral sulci.

spot, marked choking of the disks in both eyes with hemorrhages and new tissue formation and elevation of 4 diopters on both sides; third, fourth and sixth nerves, normal except for fine lateral nystagmus both to the right and to the left; fifth nerve, normal; seventh nerve, slight asymmetry of the lower facial musculature on the left with voluntary and involuntary movements of expression; eighth, ninth, tenth, eleventh and twelfth nerves, normal. Examination of the motor nerves revealed: normal gait, no paresis or paralysis, no atrophy or abnormal tonicity. Sensory examination showed normal touch, pain, temperature and vibratory sensations. The deep reflexes were slightly exaggerated on the right side; the superficial reflexes were normal. No pathologic reflexes were noted. Cerebral examination revealed: frontal lobe, slight impairment of memory and very mild euphoria; temporal lobe, normal; precentral lobe, two jacksonian attacks of the left arm; postcentral and postparietal lobes, normal; occipital lobe, attacks of transient visual hallucinations associated with nausea, vertigo and diaphoresis. Cerebellar examination revealed: suboccipital headaches; otherwise the results were negative.

*Laboratory Examination.*—The urine was normal. The Bordet-Wassermann reaction of the blood was 4-4-4; the Kahn test, ++. A roentgenogram of the skull was normal. The visual fields were normal except for enlargement of blind spot.

*Diagnosis.*—A diagnosis was made of cerebral syphilis with increased intracranial pressure.

In view of the fact that signs of intracranial pressure had developed notwithstanding considerable antisyphilitic treatment, it was felt that it was imperative to perform a decompression in order to conserve vision.

*Operation.*—A right subtemporal decompression, performed on Dec. 21, 1927, with the patient under local anesthesia, revealed markedly increased intracranial pressure.

*Postoperative Course.*—Intensive antisyphilitic treatment was continued and the choking of the disks partially receded to about 3 diopters on the right and 1 diopter on the left. Two months later, there was an increase in the elevation of the disks, with the appearance of weakness of the left arm without sensory changes.

*Operation.*—Because of the progression of the neurologic symptoms, the possibility of a neoplasm was again considered and on Feb. 24, 1928, a right osteoplastic flap operation was performed. When the dura was opened, a very remarkable picture presented itself. The convolutions were entirely flattened out and there was a perivascular thickening of the arachnoid, forming a whitish, irregular line on either side of the cortical vessels in the cerebral sulci. The appearance was as though melted paraffin had been poured on the brain and had hardened in the sulci (fig. 4). Puncture of the body of the ventricle released about 30 cc. of fluid under increased pressure. Further exploration with the ventricle-needle revealed no abnormal resistance or cystic cavities. The subtemporal decompression was enlarged and the osteoplastic flap was replaced.

*Postoperative Course.*—Strenuous antisyphilitic treatment was continued. The choking of the disks subsided in both eyes to 2 diopters. Very slight motor weakness of the left arm remained. At examination on May 31, 1928, the fundi were found to be flat with new tissue formation and secondary atrophy; visual acuity 20/50 in each eye; no headaches; no vomiting, slight weakness of the left arm. On Aug. 8, 1928, there was no headache or vomiting; the decompressed area was bulging but relaxed; there was slight weakness of the left arm.

*Comment.*—In this case, a diagnosis of tumor of the brain was repeatedly considered, and for this reason the second operation was performed. At the second operation, however, a dilated ventricle was found on the side of the suspected tumor, and instead of a tumor a well marked leptomeningitis was exposed. The intracranial pressure was due, I believe, to the interference with the circulation of the cerebrospinal fluid in the subarachnoid space, caused by the leptomeningitis, and to a resulting mild internal hydrocephalus.

*CASE 6.*—*A young woman whose husband had a history of syphilitic infection had signs of increased intracranial pressure and other localizing signs; Bordet-Wassermann reaction of the blood positive; subtemporal decompression with anti-syphilitic therapy relieved the intracranial pressure and other neurologic signs; recovery.*

*History.*—A young married woman, aged 20, was referred to me on March 23, 1928, complaining of severe headaches, vomiting and convulsions. She had been married six months before. Her husband had a definite history of syphilis, and his blood gave a positive Bordet-Wassermann reaction. About Feb. 1, 1928, the patient had been in an automobile accident, had been unconscious for two hours, and had had a miscarriage of a five months' fetus. Three weeks later she commenced to have severe frontal and suboccipital headaches. About March 1, the headaches began to be associated with vomiting and diplopia. The patient had a generalized tonic and clonic convulsion, with loss of consciousness. One week later, there was marked blurring of vision and diplopia. Twenty-four hours before examination, weakness and numbness of the left arm developed.

*Physical Examination.*—Physical examination revealed a rather slender and anemic young woman, weighing 96 pounds (43.5 Kg.). The pulse rate was 65; the temperature, 36 C. (96.8 F.), and the blood pressure, 108 systolic and 54 diastolic. The observations made on physical examination were essentially normal.

*Neurologic Examination.*—The head was normal in size and shape with no tender areas; the percussion note was normal. There was an old scar in the left parietal region, and dilatation of the veins of the upper lids. Examination of the cranial nerves revealed: first nerve, normal; second nerve, slight visual impairment, right and left, symmetrical general contraction with enlargement of blind spots in the visual fields of both eyes, choking of 3 diopters with new tissue formation; third, fourth and sixth nerves, normal except for slight bilateral exophthalmos; fifth nerve, normal; seventh nerve, lower facial weakness on the left; eighth, ninth, tenth, eleventh and twelfth nerves, normal. Examination of the motor nerves revealed: paresis of the left arm and paralysis of the left hand, no atrophy, no abnormal tonicity. Sensory examination showed: diminished sensation to touch, pain and temperature over the left hand. The biceps, triceps, patellars and achilles reflexes were hyperactive on the left side. The abdominal reflexes were inactive on the left. There were no pathologic reflexes. Cerebral examination revealed: frontal and temporal lobes, normal; precentral lobe, history of general convulsion and weakness of left upper extremity; postcentral lobe, diminished sensation in the left hand, postparietal lobe, astereognosis on the left. The occipital and cerebellar areas were normal.

*Laboratory Examination.*—The urine was normal except for faint trace of albumin; the blood count was also normal. Repeated Bordet-Wassermann tests of the blood gave a 4-4-4 reaction; the Kahn test, ++++. A roentgenogram of

the skull was normal. Visual fields showed moderate contraction with enlargement of blind spots. Spinal puncture was not made in the presence of choking of the disks.

*Diagnosis.*—A diagnosis was made of cerebral syphilis with associated increased intracranial pressure.

For one week the patient was given intensive antisyphilitic treatment. During this period the choking of the disks increased to 4 diopters right and left, and fresh hemorrhages occurred. In order to conserve the patient's vision a decompression seemed imperative.

*Operation.*—With the patient under local anesthesia, right subtemporal decompression revealed markedly increased intracranial pressure. There was a marked

Fig. 6 (case 6).—*A*, patient showing the operative scar nine days after operation; *B*, five weeks after right subtemporal decompression.

thickening of the arachnoid membrane in the cerebral sulci and several small white plaques, which gave an appearance as though melted paraffin had been poured on the brain and had hardened in the sulci (fig. 5).

*Postoperative Course.*—The choking of the disks rapidly subsided and the retinal hemorrhages disappeared. There was moderate bulging of the decompressed area (fig. 6, *A*). Intensive antisyphilitic treatment was continued. The visual acuity returned to 6/6 in each eye and the other neurologic signs completely disappeared (fig. 6, *B*). Seven months later the patient was free from general and neurologic symptoms. The Bordet-Wassermann reaction of the blood was 0-4-0. The spinal fluid showed an initial pressure of 15 cm. of water,

with a jugular compression of 28 cm. After 5 cc. of fluid was removed, the pressure was 12 cm. and the color was clear. The globulin was negative; there was no cell count; the Bordet-Wassermann reaction was ++, and colloidal gold reaction 0000000000.

*Comment.*—Extensive neurologic symptoms and increased intracranial pressure developed in a case of early syphilis. The finding of leptomeningitis at decompression suggests that this was the etiologic factor in the production of the increased intracranial pressure. Subtemporal decompression with antisiphilitic therapy relieved the intracranial pressure and the general and neurologic symptoms.

#### COMMENT

*Etiology.*—In five cases there was a definite history of a primary syphilitic infection, while in one case there was a congenital syphilitic infection. The interval between the appearance of the primary syphilitic lesion and the development of the symptoms and signs of intracranial pressure showed marked variation. In two cases, the interval was six months; in one, ten months; in one, two years; in another, nine years, and in the case of the congenital syphilitic patient, twenty-two years. Baruch<sup>8</sup> stated that in his series of cases papilledema occurred most frequently in the secondary stage of syphilis, the longest interval between the primary infection and the appearance of the papilledema in his series being sixteen years.

The signs and symptoms of increased intracranial pressure exhibited in these cases were undoubtedly associated with the syphilitic infection. In case 5, the possibility that a latent tumor of the brain was coincident with the syphilitic infection cannot be entirely ruled out; in the other five cases, however, the subsequent course thoroughly justifies the assumption of a syphilitic etiology.

*Sex and Age Incidence.*—The average age of the patients in these six cases was 27 years and 4 months, four of the patients being less than 23 years of age. Four were men, two were women.

*Symptoms.*—Severe headache was a constant complaint in these six cases. In four, the headache was described as being frontal and suboccipital; in one, it was bitemporal and suboccipital, and in the sixth case it was right parietal and suboccipital. It is interesting to note that the suboccipital location of the headache was present in every case. Frequent and forceful vomiting was associated with the headache in five of the six cases. Transient vertigo occurred in four of the cases. Transient blurring of the vision was a symptom noted by each of the six patients. They described it as a transient clouding which very

---

8. Baruch, R.: Stauungspapille bei Syphilis, ihre Ausgänge und therapeutische Beeinflussung durch Salvarsan, Deutsche med. Wchnschr. 49:186, 1923.

quickly passed away. Diplopia of the horizontal type was noted by four of the patients. This symptom was not constant. Convulsions were a striking feature of these cases. In two of the cases attacks of grand mal occurred. In one case weakness and numbness of the left arm followed such an attack, and in the other, weakness of the right side and disturbance of speech followed one attack, while after another, weakness of the left side was noted. One of the patients had attacks of the petit mal type, and later some definite jacksonian convulsions of the left arm. Another patient had attacks of sensory epilepsy of the right arm, and still another had noted frequent attacks of transient numbness of the hands and of the lower part of the face. Speech disturbance consisting of difficulty in naming objects, and a slight impairment of the ability to comprehend speech occurred in two cases. There was a history of an unsteady and mildly staggering gait in three cases, and a passing and very mild delirium had been noted in four cases.

*Objective Symptoms.*—In each of the six cases a choked disk of 3 or more diopters was found. Palsy of the extra-ocular muscles with diplopia was present in three cases and lateral nystagmus was found in two. Weakness of the lower portion of the face was noted in five cases, and in two cases there was transient loss of power in an arm, and in an arm and leg, respectively. The sensory changes consisted of paresthesia in three cases and, in one case, of an actual hyperesthesia on one side of the body. The deep reflexes were unilaterally hyperactive in four cases, in one case they were hyperactive throughout, and in one case they were normal. In two cases there were mild speech abnormalities in the form of a partial anomia and a diminished perception of speech. In three cases a slight impairment of memory was noted. Ataxia was present in four of the six cases, in the form of an unsteady gait, hypermetria, adiadochocinesia or a positive Romberg sign. Examination of the perimetric fields showed no hemianopia in any of the patients, but in three cases there were enlarged blind spots and in two, a moderate general contraction of the fields. In each case the roentgenographic study of the skull showed that it was normal. Lumbar puncture was not performed on any of these patients because of the high degree of choking of the optic disks.

The striking feature in this summary is the wide diversity of the clinical observations in the individual case. For example, involvement of the cranial nerve, sensory symptoms, aphasia and marked cerebellar signs all occurred in one patient. Furthermore, in following these cases from day to day a marked inconstancy and variability was noted in the clinical observations. Such conditions, I believe, can be produced only by a very diffuse lesion and could not be explained by the presence of a localized lesion such as a gumma.

*Pathology.*—The cause which has been generally accepted for the existence of increased intracranial pressure associated with syphilis, is the presence of a cerebral gumma. However, after a careful review of the symptomatology in the group of cases here reported, one must seek another cause. The striking point in these cases is the diversity of the symptoms and signs which indicates the presence of a diffuse pathologic condition.

The pathologic lesion which would best explain the clinical observations is a syphilitic leptomeningitis. Since all the patients made a satisfactory recovery, exact pathologic information is lacking. However, in two of the cases a marked degree of leptomeningitis was exposed at operation. In the first of these cases there was a marked thickening of the arachnoid, forming a whitish, opaque, irregular line on either side of the cortical blood vessels in the cerebral sulci. The picture was a striking one, as it looked as though melted paraffin had been poured on the brain and had collected and hardened in a thin layer in the sulci between the cerebral convolutions (fig. 4). Microscopic examination of this thickened arachnoid tissue revealed a loose fibrillar network containing numerous lymphocytes. In the other case there were whitish, opaque, multi-angular areas in the cerebral sulci over the temporal lobe (fig. 5). It is possible that this same condition was present in the other four cases of this group, for it may have been distributed over other portions of the brain even though it was not evident in the comparatively small area of the temporal lobe exposed when the subtemporal decompression was made.

In all these cases a markedly increased intracranial pressure with bulging of the brain through the dural opening was found at the time of the subtemporal decompression. In two cases in which the lateral ventricle was tapped, a dilatation was found, indicating a mild internal hydrocephalus. In three of the cases there was an excessive amount of subdural and subarachnoid fluid. In all the cases, after operation a bulging through the subtemporal decompression opening was observed, and this persisted for varying periods.

The symptoms of intracranial pressure observed in these cases, consisting of headache, choked disk and vomiting, were caused, I believe, by an obstruction of the cerebrospinal fluid circulation in the subarachnoid space, this obstruction being due to syphilitic leptomeningitis.

In a thorough study of the subject, LeCount and Dewey<sup>9</sup> (1915) found that leptomeningitis is a common complication of syphilis. They describe three types of syphilitic involvement of the pia-arachnoid: (1) opacity or turbidity, (2) patches of fibrous thickening and (3)

---

9. LeCount and Dewey: Syphilitic Leptomeningitis, *J. Infect. Dis.* **16**:142, 1915.

discrete focal lesions. Wilder,<sup>4</sup> also, in writing on the subject of syphilitic leptomeningitis, enumerated symptoms of this disease which correspond very closely to those observed in the six cases of this report, viz., headache, vomiting, vertigo, convulsions, aphasia, hemiplegia, deafness, difficulty in swallowing, psychic manifestations, mental dulness, confusion, apathy, loss of memory and even mania. This author further stated that a choked disk may be present which cannot be distinguished clinically from that seen in tumor of the brain.

*Treatment.*—Macewen was the first to practice surgical intervention in cases of cerebral syphilis. Horsley and Gowers, in 1893, advocated the surgical treatment of cerebral gummas, and Cushing<sup>10</sup> in his epoch-making contribution to the subject of surgery of the brain in his chapter in Keen's *Surgery* (1908), made the following statement concerning the relief of symptoms of intracranial pressure associated with syphilis:

I have seen a number of cases in which persistent cephalalgia has been quickly alleviated, together with a rapid subsidence of a choked disc, after a simple subtemporal decompression. This palliative measure serves, by abolishing the headache and vomiting, to so improve the patient's general condition that the medicinal treatment is far better tolerated. It, furthermore, has seemed to me to make the drug administration much more efficacious, owing possibly to the lessening of intracranial venous stasis and consequent improvement of the circulation.

In 1922, at the Congrès de la Société française d'Ophthalmologie, MM. Babinski, Chaillons, Rochon-Duvigneaud and Velter all emphasized the importance of a decompression operation in conjunction with antisymphilitic therapy in relieving choked disks occurring with syphilis.

In order to conserve vision, subtemporal decompression was performed in all the cases of my series. Following this treatment the headache, the vomiting and the choking of the disks promptly subsided. In three cases the vision was entirely normal after the choking of the disks subsided; in two cases the vision was only slightly impaired, and in one case it was moderately impaired.

If the signs and symptoms of intracranial pressure are not promptly relieved by antisymphilitic treatment, I believe that one should not hesitate to perform a subtemporal decompression. This procedure may be carried out under local anesthesia. The risk is minimal and the operation will conserve the vision of the patient, who would otherwise become blind. Strenuous antisymphilitic treatment should be continued following the decompression.

## CONCLUSIONS

1. Symptoms and signs of increased intracranial pressure may occur in syphilis and may closely resemble the clinical picture of tumor of the brain.

2. Although a gumma may be the cause of the increased intracranial pressure, there is evidence to indicate that it may also result from syphilitic leptomeningitis.

3. When signs of intracranial pressure do not promptly subside under antisyphilitic treatment, a subtemporal decompression should be performed at once.

# THE TONUS AND CONTRACTURE OF SKELETAL MUSCLES

FRÉDÉRIC BREMER

Natural (reflex) contractions of the skeletal muscles of vertebrates are apparently of two different types: "phasic" and "tonic."

The properties of the contractions of the phasic type, the voluntary contraction of man, for example, are clearly those of a neuromuscular tetanus.

The contractions of the tonic type, the so-called decerebrate rigidity of mammals, for instance, are characterized, especially, by the smallness of the phonomyographic and the electromyographic oscillations of the active muscles, their apparent indefatigability and by their plasticity which enables them to maintain the same contractile tension in widely different lengths.

The neuromuscular determinism of muscle tone is still a matter of controversy among physiologists. Two theories of its mechanism have been proposed and are still defended. For one group of investigators (Bottazi, de Boer, Langelaan, E. Frank, J. I. Hunter and Ranson),<sup>1</sup> the differences between the tonic and phasic types of sustained contraction result from a radical difference in their physiology. For these biologists, reflex tonus of skeletal muscles is, at least in part, the expression of the activity of a special contractile mechanism, quite distinct from the mechanism which is responsible for the twitch and tetanus, but of properties similar to those of the smooth muscles, and activated by a special motor innervation depending on the autonomic (vegetative) nervous system. The function of this tonic contractile mechanism, as yet ill defined morphologically (special muscle fibers [?] or sarcoplasm of the ordinary fibers [?]), would be to secure, with the minimal expenditure of energy, the fixation of contractile states at any physiologic length.

For another group of physiologists, notably Sherrington, Forbes, Cobb,<sup>2</sup> Fulton,<sup>3</sup> Adrian<sup>4</sup> and Dusser de Barenne, tonus is a proprioceptive, essentially myotatic, and postural reflex. Tonic contraction is nothing else than a partial tetanus of the muscle. Its electromyographic particularities may be explained by the complete asynchronism of the central emission of motor impulses, and consequently of the responses of the individual muscle fibers. Its apparent indefatigability would be due to

4. Adrian: *J. Physiol.* **46**:384, 1913.

a continuous rotation in the activity of the individual neuromuscular units which are engaged at any moment in the tonic reflex (Forbes). The plasticity of tonic muscle, discovered by Sherrington,<sup>5</sup> had been shown by him to be the result of the play of two proprioceptive reflexes, the shortening and the lengthening reaction, and not the expression of an intrinsic muscular property.

The experimental work of the last decade has on the whole supported Sherrington's doctrine of muscle tone. Dusser de Barenne and Burger<sup>6</sup> have proved that the metabolism of tonic contraction is not qualitatively different from the metabolism of phasic activity. Evidence of discontinuous electrical activity has been detected in practically all cases of tonic activity, lastly in the rigidity induced by tetanus toxin.<sup>7</sup> All experiments tending to demonstrate the dependence of muscle tone on a special, sympathetic or parasympathetic innervation have failed.

Still, muscle tone possesses, apart from its already mentioned characteristics, a striking sensibility to various central or peripheral conditions. It may vanish under conditions which leave the phasic contractile tension apparently unchanged; weak inhibition (Sherrington, Fulton), the action of drugs (that of scopolamine, for example, on parkinsonian rigidity), fatigue or circulatory disturbances of the muscles. In the first two cases a disturbance of the muscular receptivity is out of the question. The reasons for this special fragility of tonic innervation are not yet clear.

On the other hand, the demonstration of the fundamental identity of phasic and tonic contractions does not in itself exclude the possibility that the skeletal muscles of vertebrates have, besides their ordinary quick contractility, contractile properties allied to those of the smooth muscles and with another significance than their, erroneously supposed, tonic function.

The researches, the main results of which will be reported here, pertain to these two sides of the question.

In the first part of this paper, describing experiments made with the collaboration of Titeca and van der Meiren, the elective action of curare on reflex tone, especially in its exaggerated manifestations (hypertonias) will be described and its significance discussed.

In the second part of the article, I shall describe the results of experiments relating to the problem of the contractile duality of skeletal muscles.

## CURARE AND MUSCLE TONE

*The Elective Action of Curare on Decerebrate Rigidity.*<sup>8</sup>—The starting point of our researches was the observation that it was possible, by the intravenous injection of a very small dose of curare ( $\pm 0.25$  mg. per kilogram), to abolish or to diminish considerably the extensor rigidity of decerebrate cats, without apparently affecting their phasic motricity. The contrast of the general flaccidity of these animals with the apparent vigor of all their bulbar and spinal reflexes was striking because generally when decerebrate rigidity vanishes spontaneously, either it is replaced by a condition of flexor tone with the disappearance of the crossed extensor and other allied extensor reflexes, or it is only one of the symptoms of a general depression of the nerve centers and is accompanied by a weakening or abolition of all reflexes, especially the extensor ones.

Fig. 1.—Crossed extensor reflexes and neuromuscular tetanus of the isolated gastrocnemius muscle of decerebrated cats. Isometric records taken with the Sherrington torsion wire myograph. In these and in all the subsequent records of reflexes, the beginning of the faradic maximal stimulation of the central stump of the sciatic nerve is marked by the movement of the signal line downward. The time at which each reflex is elicited is written immediately under the signal line. The distance of the secondary coil is marked above it. Time is given in second intervals. *A* shows the curve of the reflex of a decerebrate rigid cat; *B*, of the gastrocnemius muscle of a decerebrate rigid cat. All the muscles of the calf and of the thigh had been deafferented by the aseptic section, thirty-two days previously, of the posterior roots of the fifth, sixth and seventh lumbar and first sacral nerves. The limb was entirely atonic. Note the persistence of the true after-discharge, and the complete disappearance of the tonic pseudo-after-discharge (shortening reaction). *C* shows the curve of neuromuscular tetanus of the gastrocnemius muscle chosen from the same contractile tension as the two preceding reflexes. Reduced one-third.

The elimination of such small doses of curare is rapid, so that after twenty to thirty minutes the extensor tonus begins to reappear, and after forty-five to sixty minutes the rigidity may have regained its original degree.

8. Bremer; Titeca and van der Meiren: *Compt. rend. Soc. de biol.* **96**:275, 1927.

The phenomenon may be objectivated by the myographic registration of the crossed extensor reflex of the cat. The reflex, evoked by a maximal faradic stimulation of the sciatic nerve on one side, is characterized by the prolongation of its contraction into a lasting pseudo-after-discharge, which is nothing else, as Sherrington<sup>5</sup> has shown, than a tonic shortening reaction, grafted on the phasic reflex contraction (figs. 1, 2 and 3). The precocity, intensity and duration of this tonic pseudo-after-discharge are proportional to the intensity of extensor rigidity and constitute a valuable index of it.

Fig. 2.—Two crossed reflexes of a decerebrated rigid cat, weighing 2.9 Kg.; A, curve taken before the intramuscular injection into the upper third of the gastrocnemius muscle, of 0.2 cc. of a 1 per cent solution of procaine hydrochloride in Ringer's serum, and B, seven minutes afterward, a marked weakening of the shortening reaction (atonia) is visible. Reduced one-third.

Fig. 3.—The three constituents of the crossed extensor reflex: (1) in white, the reflex tetanus; (2) in horizontal hatching, the true after-discharge, and (3) in vertical hatching, the shortening reaction (tonic pseudo-after-discharge) which disappears, when the muscle is insensitized, and which is especially sensitive to curare.

Figure 4 shows the crossed extensor reflex, isotonicly registered on a slowly moving drum, of the isolated vastocrureus of a rigid cat before (A) and during (B) the action of a weak dose of curare. As one sees it, the reflex of the curarized animal, though of the same myographic amplitude as before, is entirely deprived of tonic after-discharge, purely phasic. Figure 4C shows the recovery of the normal tonic features of the reflex, fifty minutes after the injection. In this experi-

ment the same elective action of curare on decerebrate rigidity, followed by the recovery of tone after about forty-five minutes, was observed three times.

Isotonic myograms cannot give accurate information on the possible degree of electivity of this action of curare on decerebrate rigidity. To obtain such information it is necessary to record the tensions developed, respectively, by the phasic reflex and its tonic after-discharge. Figure 5 reproduces such isometric myograms taken at regular intervals after the injection of the drug. They show the rapidity of the action of curare on the shortening reaction, whose progressive weakening contrasts with

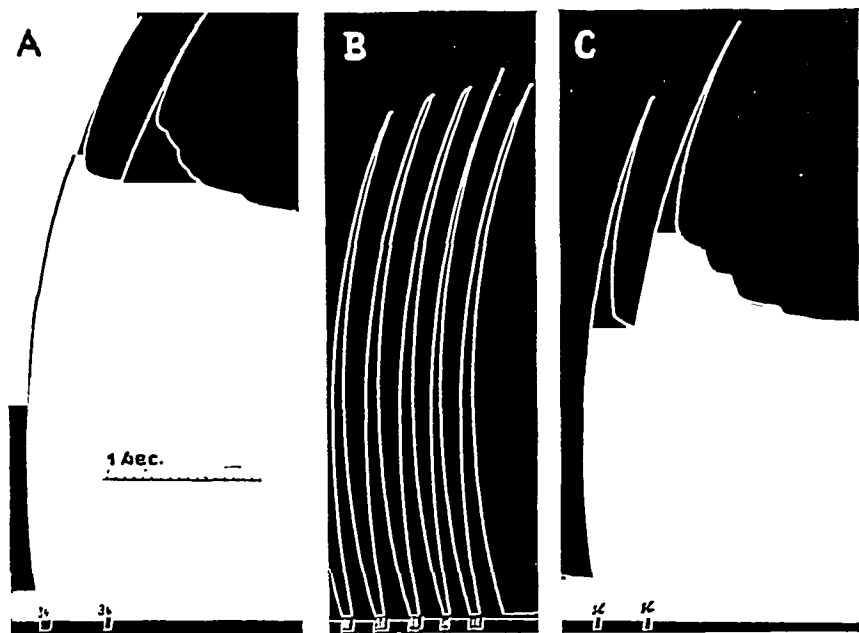

Fig. 4.—Crossed extensor reflexes of the isolated vastocruureus muscle of a decerebrate cat, weighing 3.5 Kg. Isotonic records. *A* shows curve made before curarization. Marked extensor rigidity is shown by the strong shortening reaction. *B* was made eight minutes after the injection of 1 mg. of curare in the jugular vein. Animal is atonic. There is a complete disappearance of the shortening reaction. *C* was made twenty minutes after the injection of curare. Animal is nearly as rigid as before. Reduced two-thirds.

the unchanged height (contractile tension) of the phasic part of the reflex. Only at a later stage of the intoxication, the reflex plateau begins to sink down during stimulation, the characteristic muscular fatigability of curare intoxication.<sup>9</sup> Tonic after-discharge, though considerably reduced, had not yet entirely disappeared at this moment in this case.

9. Hofmann: Arch. f. d. ges. Physiol. 93:136, 1903; 95:484, 1903.

Figure 6 shows a series of myograms of the crossed extension reflex taken in succession at different initial tensions: *A*, before, and *B*, during the intoxication. The special sensibility of the tonic after-discharge is manifest. This is also apparent in figures 9 and 10.

Fig. 5.—Progressive disappearance of the tonic shortening reaction, and of decerebrate rigidity, after an injection of 0.18 mg. of curare per kilogram at 4:05 o'clock and a second one of 0.06 mg. at 4:25 o'clock. *A* shows curve of crossed extensor reflex (isometric record) of the isolated gastrocnemius muscle before curarization; *B*, *C*, *D*, *E* and *F*, of reflexes evoked by the same maximal stimulus of the sciatic nerve at the different stages of curarization. Reduced one-third.

Fig. 6.—Crossed extensor reflexes of the isolated gastrocnemius muscle evoked by the same maximal stimulus at different initial tensions of the muscle: at left, before curarization; and at right, during curarization (0.37 mg. per kilogram). Reduced one-third.

Other experiments have convinced us moreover that the height of the simple maximal neuromuscular twitch (isotonic) may be absolutely unaffected at a stage of curarization when decerebrate rigidity has entirely vanished.

*Elective Action of Curare on the Rigidity of Local Tetanus.*<sup>10</sup>—It was interesting to verify that another reflex hypertonia, though quite different from that of decerebrate rigidity in its determinism, was also electively sensitive to curare.

The reflex hypertonia of local tetanus has been found, in our experiments, as electively sensitive to curarization as decerebrate rigidity. Cats and rabbits were given injections, subcutaneously or intramuscularly, of an appropriate dose of tetanus toxin in one of the hind limbs. A local rigidity developed in the muscles of the region or muscles in which the injection was made (fig. 7 *A*). From the second to the fifth day after the injection, when this rigidity was still entirely, or for the greatest

Fig. 7.—Elective action of slight curarization on the rigidity of local tetanus. On May 3, 1927, at 6 p. m., this rabbit, weighing 850 Gm., was given an injection, under the skin of the left thigh, of 0.02 cc. of a toxin capable of killing a mouse in the dosage of 0.001 cc. On May 5, 1927, a rigidity of the thigh was manifested. On June 5, 1927, the date of the experiment with curare, the rigidity was extreme, woodlike. *A* shows the animal at 11 a. m. before curarization; *B*, at 12:25 p. m., one hour after the subcutaneous injection of 0.25 mg. of curare. There has been a complete disappearance of the stiffness of the left thigh. The attitude and strength are apparently normal. Fatigability is noted. *C* shows the animal at 11:45 a. m., completely atonic, though still capable of walking (twenty minutes after the injection of curare, the dosage being slightly excessive). At 2 p. m. the stiffness of the left thigh was as marked as before.

10. Bremer; Titeca and van der Meiren. *Compt. rend. Soc. de biol.* **97**:895, 1927.

part, a reflex hypertonia (Meyer and Ransom), it was sufficient, in order to abolish or considerably diminish it, to inject subcutaneous doses of from 0.2 to 0.3 mg. of curare per kilogram. These doses had only a slight effect on phasic motricity and might even leave normal tonus (attitude) unchanged (fig. 7 B). The action of the drug is maximal in from thirty to sixty minutes after the subcutaneous injection and is perceptible for about two hours. The effect of the injection of one and the same dose weakens from day to day on account of the transformation of the primary reflex hypertonia in an irreversible myogenic contracture. When the transformation is complete (in our experiments from the seventh day onward), curare, in any dosage, has no effect on the rigidity.

This electivity of curare on the spasticity of local tetanus would seem to justify its therapeutic use in human tetanus, a use which, as a matter of fact, has been tried from time to time; and even in other conditions of neurogenic muscular spasticity. The narrowness of the margin, however, between therapeutic and dangerous doses, the variability in the stocks of curare, the difficulty of preparing its pure alkaloids, and also the common presence in cases of tetanus, in human beings, of symptoms of general (phasic) reflex hyperexcitability, make this method actually unsafe.

*The Action of Curare on Normal Reflex Tonus.*<sup>2</sup>—Normal muscle tone of an intact animal is not as electively sensitive to curare as are decerebrate and tetanus rigidities. Certainly, the loss of postural tone is the dominant symptom of the slight and reversible curarization of vertebrates. It shows itself in frogs, given intravenous injections with a minimal dose, by the contrast which exists between the general muscular flaccidity of the animal and the energy of its jumping; in rabbits by the drooping of the ears, a symptom which Boehm has already noted as the earliest one of progressive intoxication, then by the sinking down of the whole body, which is spread out along the ground (fig. 7 C), and by the manifest flabbiness of the musculature. But at this stage of intoxication, the animals, though still capable of efficient contractions, exhibit a degree of paresis which cannot be accounted for by mere hypotonia. Still weaker doses determine only a characteristic fatigability of the animals.

*The Possible Mechanism of the Elective Action of Curare on Normal and Exaggerated Muscle Tone.*—Because of the classic properties of curare, comment may be restricted to a few possible explanations.

An effect on afferent or central mechanisms is excluded by their well known integrity in much deeper stages of intoxication. The action of such small doses of curare must be confined to neuromuscular junctions.

In view of the theory of an autonomic innervation of tonus, the possibility of an action of the drug on these hypothetical neuromuscular junctions must first be discussed. This hypothesis may be easily dismissed, for neuromuscular junctions of the autonomic nervous system are all notoriously much less susceptible to curare than are the ordinary junctions of skeletal muscles. Besides, it has been repeatedly proved that ergotamine and atropine, the two classic paralyzing alkaloids of the sympathetic and parasympathetic neuromuscular junctions, are without any peripheral effect on muscle tone. We have verified this fact concerning scopolamine on decerebrate rigidity. We have been unable to confirm the assertion of Ranson<sup>1</sup> that local applications of a solution of nicotine on the posterior root ganglions, where he located a hypothetical synaptic junction of the tonic efferent path (Frank<sup>11</sup>), abolish or diminish decerebrate rigidity of the cat (figs. 3, 4 and 5).

The only alternative which remains then is that the atonia of the early stage of curarization is the result of the classic action of the poison on the ordinary neuromuscular junction of the skeletal muscle fibers.

Our working hypothesis, suggested by researches of Forbes and Olmstead,<sup>12</sup> has been that the motor innervation of tonus and reflex rigidities, though utilizing, as the phasic one, the final common path of the ordinary motoneurons, is essentially made up of impulses of a very high frequency but of subnormal amplitude,<sup>13</sup> and therefore is more easily blocked than impulses of a smaller frequency, at the curarized neuromuscular junctions. A light curarization, therefore, would operate by the mechanism of the Wedenski inhibition, a kind of filtration of the nervous impulses at the intoxicated neuromuscular junctions. At an initial stage of curarization (realized by the injection of an appropriate small dose of the poison), the motor impulse of the tonic innervation could be already blocked, when isolated impulses, and most of the impulses of smaller frequency and therefore of greater amplitude of the phasic innervation would still be able to pass the junction (to excite the muscle fibers).

The experimental verification of this hypothesis<sup>14</sup> has shown us that the matter is more complex than we thought it at first. Curare alone, contrary to our expectation, and apparently to the classic opinion,<sup>8</sup> does not seem to create in frogs and cats the condition of a Wedenski inhibition, if one judges from its absence of effect on the least interval for neuromuscular summation and on the whole Lucas-Adrian recovery curve, at least when any fatigue of the neuromuscular preparation is

12. Forbes and Olmstead: *Am. J. Physiol.* **73**:17, 1925.

13. Lucas, K.: *The Conduction of the Nervous Impulse*, London, Longmans, Green & Co., 1917, p. 83.

14. Bremer and Titeca: *Compt. rend. Soc. de biol.* **97**:1407, 1927.

avoided. But fatigue, as is well known, and verified, does increase the least interval, and, much better still, the combination of fatigue and curarization (fig. 8). The continuous arrival of tonic impulses to the muscle must result in a condition of fatigue of the neuromuscular junctions, which curarization seems to intensify considerably. Thus the condition of a selective blocking of the high frequency impulses of tonic innervation at the early stage of curarization can be recognized.

This explanation takes satisfactory account of the fact that decerebrate and tetanus rigidity are distinctly more sensitive to curare than normal postural tone. These two types of spasticity have only in common in their determinism that both are the expression of an excess of tonic innervation of the stiff muscles. This excess of reflex innervation in the final analysis must resolve itself into: (1) an augmentation of the

Fig. 8.—Neuromuscular recovery curves of the sciatic nerve and gastrocnemius muscle of a brown frog weighing 40 Gm., recorded by the method of Lucas and Adrian. The abscissa shows the resistance of the primary coil giving the intensity of the second breakshock; the ordinate, the interval between the two stimuli. The first stimulus is a slightly supramaximal breakshock of a coreless coil; the second, the breakshock of variable strength of another identical coil. The rupture of the two primary coils was made with Lapique's rheotome (chronaximètre), transformed in double interrupter. On the left appear the curves of the right sciatic nerve of a decerebrate frog recorded before (circles) and immediately after (triangles) sixty seconds' tetanization of the muscle, whose circulation is intact; on the right, similar curves of the left sciatic nerve and gastrocnemius muscle recorded after the curves for the right side. Between the recording of the curves of the unfatigued muscle (circles) and the recording of the curve of the fatigued muscle (triangles), an intravenous injection of 0.008 mg. of curare has been made. The last curve, therefore, is that of the lightly curarized and fatigued muscle. It shows a distinct discontinuity and an enlargement of the least interval for tetanic summation, which are the conditions of the Wedenski inhibition (Adrian).

number of motor fibers occupied by the tonic reflex, and (2) an increased frequency of the motor impulses transmitted by each fiber individually.

On the whole, these experiments on curare give additional evidence of the fundamental identity of phasic and tonic innervation, both being of tetanic nature and utilizing the same motor fibers. But they show also the possibility of an elective blocking, at the initial stage of curarization, of the motor impulses of reflex tonus, and especially of reflex hypertonias. From this elective action of curare, it may be inferred that the motor impulses of tonus must have some particularity which distinguish them from the motor impulses of phasic contractions. In our hypothesis, which is not contradicted by the experimental evidence at hand, this particularity of the tonic impulses is their small amplitude, a consequence of their especially high frequency.

#### EPINEPHRINE AND MUSCULAR ATONIA CAUSED BY SMALL DOSES OF CURARE

The fact that muscle tone is independent in its motor innervation from the autonomic nervous system does not, of course, exclude the possibility of an autonomic, specially sympathetic, innervation of skeletal muscle fibers having another definite function.<sup>15</sup>

The well known morphologic work of Tchirief, Bremer, Boecke, Agduhr, Kulchitsky, Hunter, Kuntz and Herper (see Weed<sup>16</sup>) makes such an innervation probable. The remarkable results of Orbeli and his pupils,<sup>17</sup> though still needing confirmation, point to a trophic, dynamogenic and defatigating action of this sympathetic innervation.

The dynamogenic effects of epinephrine on skeletal muscles has been considered by many physiologists, notably Cannon, Gruber,<sup>18</sup> and Guglielmetti<sup>19</sup> as mimetic of this sympathetic revigorating action. But for other investigators, lastly, Wastl,<sup>20</sup> this dynamogenic action of epinephrine on normal or fatigued muscles of mammals, besides being inconstant, may be entirely explained by the cardiomuscular effects of the alkaloids and the resulting betterment of muscle circulation. (Our experiments with epinephrine on lightly curarized cats may be of interest in the controversy because they show a muscular action of epinephrine which cannot be explained, we think, by hemodynamic factors.)

The existence of an epinephrine-curare antagonism was described by Panella,<sup>21</sup> De Fonseca,<sup>22</sup> and Gruber.<sup>23</sup> In their experiments, the neuro-

muscular excitability, abolished or greatly diminished by curare, was more or less completely restored by epinephrine. But, probably on account of the somewhat high doses of curare which were necessary in order to influence the neuromuscular excitability for single shocks, the antagonistic effect was not always distinct.

Observing that the degree of extensor tone was, every other factor being unchanged, a delicate index of the degree of curarization of the decerebrate rigid cat, we thought that it would be interesting to determine whether epinephrine has any antagonistic action on this curare atonia. The experiment was further justified because epinephrine, as is known, is without appreciable constrictive action on the blood vessels of nerve centers, a fact which our own observations indirectly confirmed.

We have observed the following facts: Intravenous injections of epinephrine hydrochloride in various doses to normal (uncurarized) decerebrate cats, had only occasionally a dynamogenic action on phasic

Fig. 9.—Action of epinephrine on the curare atonia of the cat. The records are approximately isometric. *A* shows curve of crossed extensor reflex before curarization; *B*, the same during the curare atonia. Intrajugular injection of 0.05 mg. of epinephrine hydrochloride were given at the point indicated by the arrow. Reduced one-half.

and tonic contractility, and more often exhibited a depressive action, which was probably the expression of its vasoconstrictive properties for muscular blood vessels. But when injected in the same doses into animals in the state of curare atonia, it showed a remarkable decurarizing effect, attested by the transitory reappearance of decerebrate rigidity, generally unaccompanied by an increase of the phasic contractile tension. This effect, which is nearly constant when observed visually or by palpation, could be myographically recorded (figs. 9 and 10) in about one third of the total number of seventy-two injections. It is almost immediate and rarely lasts more than one minute, sometimes less. For this reason, it has often escaped myographic registration.

We think that this restoring effect of epinephrine on the atonia of the initial stage of curarization is the expression of a true muscular antagonism of epinephrine and curare for the following reasons: 1. No

increase of blood pressure was, in our experiments, able to influence the curare atonia. Besides, the minimal doses of curare used do not affect blood pressure. 2. In order to obtain the effect, it was necessary to inject quickly into the jugular vein  $\pm 0.08$  mg. per kilogram of epinephrine hydrochloride, a dose which was considerably higher than the dose sufficient to provoke marked cardiovascular effects. The same fact had been noted already by Gruber<sup>18</sup> in his study of the epinephrine fatigue

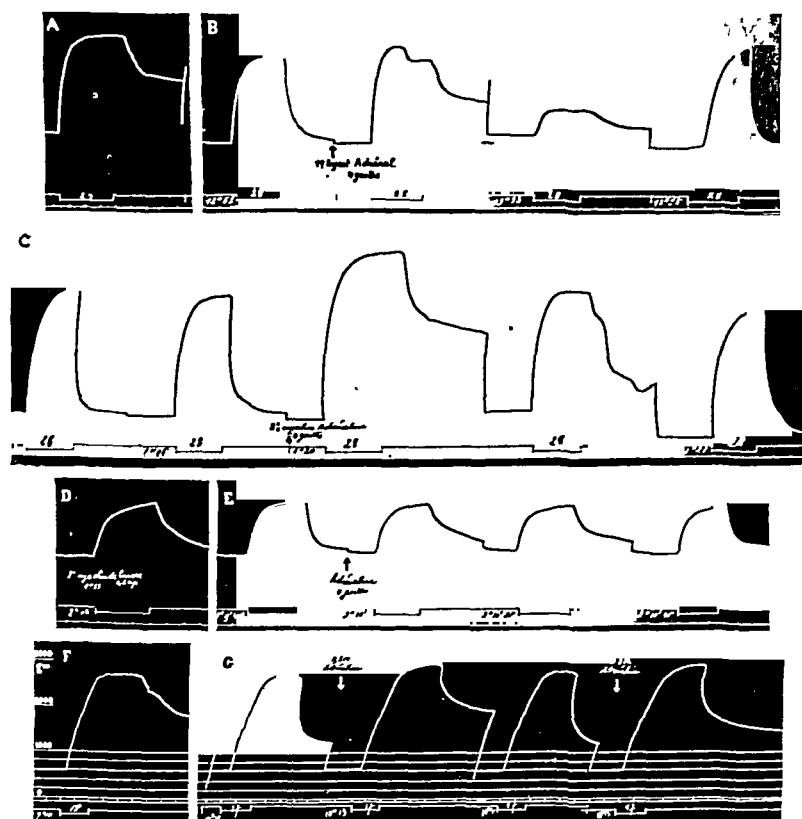

Fig. 10.—Action of epinephrine on the curare atonia. The first three rows are approximately isometric myograms of the crossed extensor reflex. The myograms of the fourth row are strictly isometric (torsion wire myograph). The first two rows of reflexes were recorded in the same experiment. The reflexes *A*, *D* and *F* were taken before curarization, on the rigid decerebrate cats, all the others during curare atonia. Injections of epinephrine ( $\pm 0.08$  mg. per Kg.) were given at the point indicated by the arrows. Reduced one-half.

antagonism in the cat. 3. The effect on tonus was much more transitory than the hemodynamic phenomena, even when it was not followed by a depressive effect (figs. 9 and 10, *D* and *E*). It seems that, as in the

experiment of Gruber just mentioned, the attainment of a liminal concentration of the hormone in the close vicinity of the muscle fibers, is the condition of its efficient antagonistic effect.

If it is granted that epinephrine is able to reestablish by a direct action on the muscle, the neuromuscular transmission impaired by light curarization, it seems probable, in view of the similarity of action between curare and fatigue, that its dynamogenic effects on fatigued muscles, are also due, at least in part, to a direct action of the hormone on the skeletal muscle fibers or on the neuromuscular junctions.

This may be considered as a new argument, worthy of consideration, though indirect, in favor of a sympathetic muscular innervation of skeletal muscles and its trophic, restoring function.

#### CONTRACTILE DUALITY OF SKELETAL MUSCLE FIBERS

*The Neuromuscular Contracture.*—The main argument of the physiologists who believe in the existence of a contractile duality of the skeletal muscles is the ease with which it is possible to induce reversible contractures, or show contractions, of the muscles of different vertebrates. Particularly interesting from this point of view are the contractures resulting from stimulation of amphibian muscles, either by appropriate direct electrical stimuli (contracture then prolongs the twitch or succeeds it) or by alkaloids acting at the neuromuscular junctions and determining at once a contracture; as, for example, nicotine,<sup>24</sup> acetylcholine<sup>25</sup> and numerous other bases of similar properties.<sup>26</sup> But, curiously enough, it had been found impossible, except for the so-called fatigue contracture, the determinism of which is complex, to obtain similar contractures or slow contractions by stimulating the motor nerves of the same muscles.

This fact, which had already been strongly emphasized by Tiegel,<sup>27</sup> has been confirmed many times, notably by Langley.<sup>24</sup>

Yet, human pathology affords an instance of a contracture which is apparently provoked by nervous impulses and, at any rate, is not the result of muscular fatigue, for, on the contrary, fatigue tends to abolish or diminish it; it is the contracture of Thomsen's disease and other allied "myotonias."

I could find the reason for the failure of the previous attempts to induce contracture of the skeletal amphibian muscles by nervous stimulation. As a matter of fact, it is easy to provoke regularly, by nervous

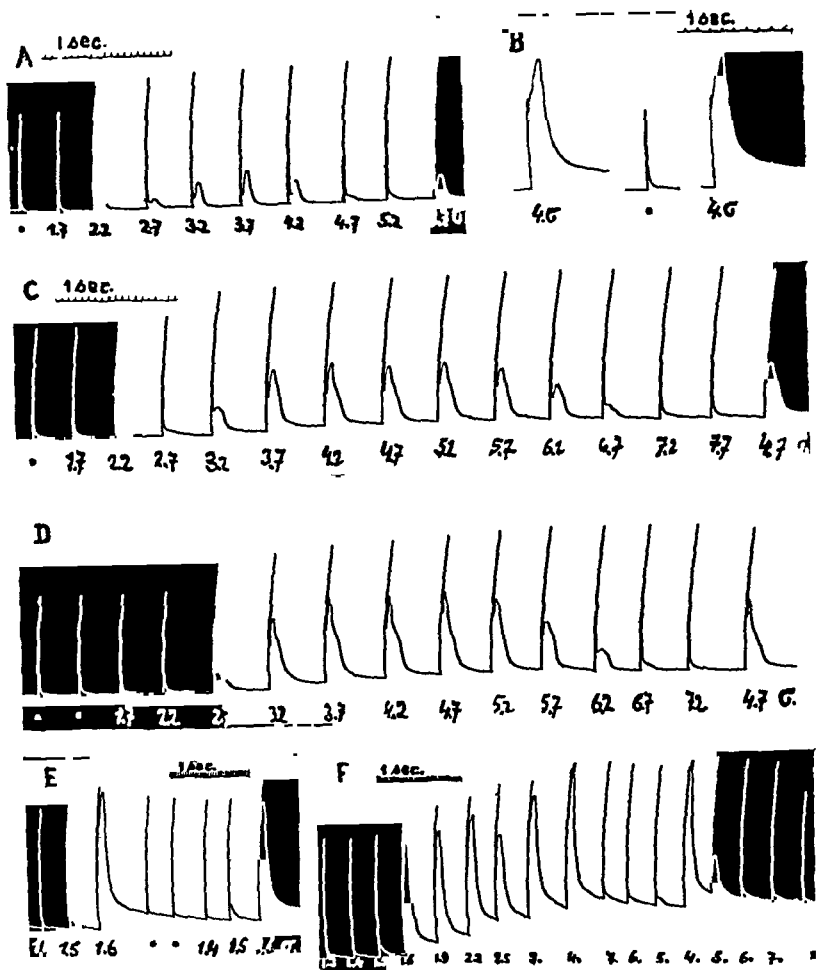

Fig. 11.—Neuromuscular contracture of the brown frog. In these, and all subsequent tracings, the simple (isotonic) twitches of the gastrocnemius, provoked by a single maximal breakshock on the nerve, are marked by a point under their myogram; the double fused twitches in answer to a succession of two maximal breakshocks are each marked by a number indicating in sigmas and tenths of a sigma the interval of the two stimuli. Reduced one-third. *A*, *C*, *D* and *F* show the regularity of the increase and decrease of the slow contraction (neuromuscular contracture) with the increase of the interval between the two stimuli, in other words, the strict dependence of the height of its myogram on the interval of the two stimuli, consequently of the interval of the two nervous impulses. The second and third rows of myograms were taken on the same frog at intervals of one hour. The temperature was 13 C. In all the figures, the constancy of the minimal, optimal and maximal intervals of the stimuli giving a neuromuscular contracture is striking. The myograms of figure 12 *E* and *F* show particularly well the identity of the minimal interval, with the least interval for tetanic summation (absolute refractory period of the nerve (which was of 1.5 sigma. The 1 sigma interval was too small for tetanic summation, as well as for the summation of impulses which evoke a neuromuscular contracture. In *A*, the muscle appears quite fresh; the twitches reproduced were the first ones of the experiment. In *B*, *C*, *D*, *E* and *F* the muscle had been tetanized previously (sometimes many hours before) for five to fifteen seconds. The temperatures were respectively: in *A*, 14 C.; in *B*, 17 C.; in *C* and *D* (the same muscle), 13 C.; in *E* and *F* (the same muscle), 20 C.

means, a slow contraction which is more or less prolonged in contracture of the amphibian muscles. One must make a summation of two or more nervous impulses, and utilize, as the object, the sciatic nerve and gastrocnemius muscle of recently captured brown frogs (*Temporarias*) or of toads.

When the sciatic nerve of a neuromuscular preparation of a green frog (*Esculenta*) is stimulated with two maximal breakshocks of adjustable increasing distance, starting, for example, from 0.5 sigma and increasing each time by intervals of 0.5 sigma, the myograms of the twitches isotomically recorded on a slowly moving drum, have at first the height and duration of the simple maximal twitch because the second stimulus is ineffective; then, when the absolute refractory period is over, and when a tetanic fusion of two twitches ensues, the height of the myograms becomes greater than that of the simple twitches and increase regularly, up to a maximum, with the increase of distance of the two breakshocks. On the slowly moving drum, their parallel increase of

Fig. 12.—Neuromuscular contracture of the fresh gastrocnemius muscle of a brown frog. The twitches were recorded in succession every minute. Temperature, 15 C. Reduced one-half.

duration is not perceptible. These facts are classic, and they were found perfectly true in our experiments on neuromuscular preparations of green frogs, either fresh or preliminarily tetanized during a few seconds.

But when the same experiment is done on the sciatic nerve and gastrocnemius muscle of a brown frog, especially after a short tetanization, a remarkable phenomenon is revealed: The simple maximal twitches provoked either by a single maximal stimulus or by two stimuli insufficiently spaced, show nothing in particular, neither do the double fused twitches in answer to two stimuli more than  $\pm 8$  sigmas apart. But the twitches evoked by stimuli spaced, from the least minimal interval of tetanic summation ( $\pm 2$  sigmas at ordinary room temperature) to  $\pm 8$  sigmas, are all immediately followed by a slow secondary contraction (figs. 11, 12, 15 and 16), more or less ending in a contracture (figs. 11 B and F, 15 A, B and C), perfectly regular in its myographic shape, and of a height and duration which is a function of the distance of the stimuli; increasing at first up to a maximum, corresponding to an

optimal interval ( $\pm 3.5$  sigmas at ordinary temperature), then decreasing gradually and generally disappearing at an interval of 8 sigmas (figs. 11, 12, 15, 16). The regularity and constancy of this increase and decrease are surprising (figs. 11 *A*, *C*, *D*, *F*, and 12). The myographic features of this slow secondary contraction or neuromuscular contracture,<sup>28</sup> as I call it, recall the curves of the Tiegel contracture which is provoked, as one knows, by the direct stimulation of the frog muscles with a single strongly supramaximal breakshock; and also recall, but less exactly, the familiar veratrin curves. The height of its isotonic myogram may surpass, and sometimes considerably (figs. 11 *B*, 12 and 16 *D*), the height of the maximal fused twitch on which it is grafted, often submerging it (figs. 15 *A* and 16 *D*).

*Determinism and Pharmacologic Properties of the Neuromuscular Contracture.*—The mere fact that the simple maximal twitches and the double fused twitches in answer to two stimuli more than 8 sigmas apart, at ordinary temperature, are never followed by a slow secondary contraction, shows immediately that this slow contraction is not a consequence of the twitch to which it is necessarily associated, but has its own special determinism. This induction is confirmed by the fact that the law of its stimulation is strikingly similar (fig. 13) to the law of summation (addition latente) of nervous impulses which I found when studying this last phenomenon on incompletely curarized muscles.<sup>29</sup>

The explanation of the relation of the height of the secondary contraction, the neuromuscular contracture, to the distance of the two maximal stimuli on the nerve would be then as follows: A single volley of impulses, that is, a single impulse in each nerve fiber, evokes only the ordinary brief twitch of the nerve. Two successive volleys of impulses determine, besides the double-fused twitch, a slow secondary contraction by excitation of the slow contractile mechanism which is sensitive only to a summation of nervous impulses. Its height increases first with the interval of the two volleys (the two impulses in each nerve fiber), because the amplitude of each second impulse increases with the increase of its interval from the first (progressive recovery of the nerve fibers). This greater amplitude makes it a better stimulus for the slow contractile mechanism, which is activated in an increasing number of neuromuscular units. A succession of stimuli, however, when their intrinsic strength does not depend on their frequency, is always less effective when their interval increases. There must be a limit, then, to the increase of height

28. I chose these terms in order to recall together the neuromuscular determinism and the slowness of the secondary contraction (especially in its decontraction). The expression, "neuromuscular slow secondary contraction" would have been more exact, perhaps, but is not convenient.

29. Bremer, F.: *Compt. rend. Soc. de biol.* **97**:1179, 1927; **98**:601, 607, 612 and 1264, 1928. Bremer and Rylant: *Ibid.* **90**:982, 1924.

of the secondary contraction with the increase of interval of the two stimuli. And after an optimal interval, this height must decrease, because summation of impulses fails in an increasing number of neuromuscular units. But of course, the summation<sup>30</sup> of responses (tetanic fusion of the two twitches) does not fail at all, and the height of the fused brief twitch continues to increase with the interval of the two stimuli, while the slow contraction ceases to be evoked when the interval exceeds  $\pm 8$  sigmas (at ordinary temperature). As already pointed out, this fact shows clearly the independence of the determinisms of the brief and slow contractions.

Fig. 13 A and B.—Lightly curarized sciatic nerve and gastrocnemius muscle (in situ) of two green frogs. Isotonic myograms of the twitches were recorded on an arrested drum. At this stage of curarization the single maximal breakshock on the nerve provoked no response of the muscle, but two such stimuli when adequately spaced gave a twitch through the mechanism of summation of impulses. Note the striking analogy of the law of summation, in this case, with the same law in the case of the neuromuscular contracture: the same least interval, coincident with the duration of the absolute refractory period, and the same optimal interval, in which the summation of impulses succeeds in the greatest number of neuromuscular units. Single stimuli are indicated by points; double stimuli by their interval in sigma.

30. As is well known, summation of responses (the muscular tetanus) and summation of stimuli (or of impulses) are entirely different phenomena and it would be highly desirable to adopt two different designations for them in order to avoid confusion.

Fig. 14.—*A* shows that two maximal stimuli on the sciatic nerve of a brown frog gave only a trace of neuro-muscular contracture; *B*, that a rapid succession of  $\pm$  six stimuli gave a distinct contracture. *D*, *E* and *F* show the influence of the frequency of nervous tetanization on neuromuscular contraction. The frequencies were successively of eight, thirty and sixty breakshocks per second. *C* shows the neuromuscular tetanus of the gastrocnemius muscle of a green frog (isotonic); *G*, the neuromuscular tetanus of the gastrocnemius muscle of a brown frog showing strong neuromuscular contracture (figs. 15 *A*, *B* and *C*). Reduced one-half.

The neuromuscular contracture is then the answer of the muscle to an appropriate summation of nervous impulses. When a pair of such impulses is not sufficient to evoke a slow contraction, a greater series of them, adequately timed, may succeed (fig. 14).

The necessity of such a summation of impulses to evoke a neuromuscular contracture of the gastrocnemius muscle (or other muscles innervated by the sciatic nerve) of the brown frog or of the toad may be understood if one considers the facts in the light of recent neurophysiologic knowledge. The secondary contraction is apparently the

Fig. 15.—Elective fatigue of the neuromuscular contracture. *A* shows that in a quick succession of double fused twitches at the optimal interval for neuromuscular contracture the last twitch rapidly disappears and recovery is complete after a rest of two minutes. *B* and *C* show the less pronounced fatigability of neuromuscular contracture for a similar quick succession of twitches not followed by contracture; either single maximal (*B*) or double fused twitches (*C*) evoked by stimuli whose interval is too great (15 sigmas) for neuromuscular contracture. *G* indicates the elective action of scopolamine (5 mg. given intravenously) on the neuromuscular contracture of a brown frog weighing 50 Gm. Double fused twitches at the optimal interval were recorded every two minutes. An injection of scopolamine was given at the point indicated by the arrow. Reduced one-fourth

manifestation of the activity of a slow contractile mechanism. Its regular myogram, which lasts from three to four seconds and longer, recalls the slow "twitches" of smooth muscles. It is a general law, well demonstrated by Lapicque and his school,<sup>31</sup> that slow contractile mechanisms are also slow in their excitability, in other words, have a great chronaxie. This means that in order to excite their contraction, electrical waves must have an appreciable minimal duration.

As a matter of fact, in the skeletal muscles of amphibians, the existence of a slow contractile mechanism and of its slow excitability is proved by their reaction to direct electrical stimulation. The gastrocnemius muscle of the frog which responds to currents of brief duration, for example, to single break induction shocks, by a simple brief twitch,<sup>32</sup> when directly stimulated with currents of an appreciable duration, shows marked contractions characterized by a greater or lesser prolongation in

Fig. 17.—The action of atropine (6 mg. of atropine sulphate intravenously) on the contracture which follows the neuromuscular tetanus of the brown frog (a succession of tetani of five seconds from sixty breakshocks per second, separated by rests of five seconds). The contracture which atropine prevents is neuromuscular contracture. The remaining contracture is true fatigue contracture. *A* shows the myogram of the right gastrocnemius muscle, before and after the injection of atropine. *B*, the myogram of the left gastrocnemius muscle, recorded five minutes after the injection. Normally, the intensity of the maximal post-tetanic contraction of the homologous muscles of both sides is equal. Reduced three-fifths.

contracture. Neither curare nor atropine modify this ability of direct contracture (fig. 18).

I have verified the fact that the aptitude of amphibian muscles to neuromuscular contracture is strictly proportional to their tendency to contracture on direct electrical stimulation. The gastrocnemius muscle of green frogs, which in our experience has not exhibited neuromuscular

31. Lapicque: *L'Excitabilité en fonction du temps*, Paris, 1926, p. 358.

32. Biederman: *Électrophysiologie*, 1895, chapt. 2.

contracture, shows much less contracture from direct galvanic current than the muscles of the brown frogs and toads; and in the latter, the greater the aptitude is for neuromuscular contracture, the greater is it also for contracture evoked by direct adequate stimuli. In some cases, this aptitude for contracture was so marked that the contracture appeared isolatedly at the threshold strength of current, as a slow contraction (fig. 18); I could determine, in a few experiments, the chronaxie of the slow contractile mechanism. As could be anticipated, I found rather high values for it:  $\pm 35$  sigmas at 16 C. in one experiment and  $\pm 70$  sigmas at 11 C. in another as compared with the values

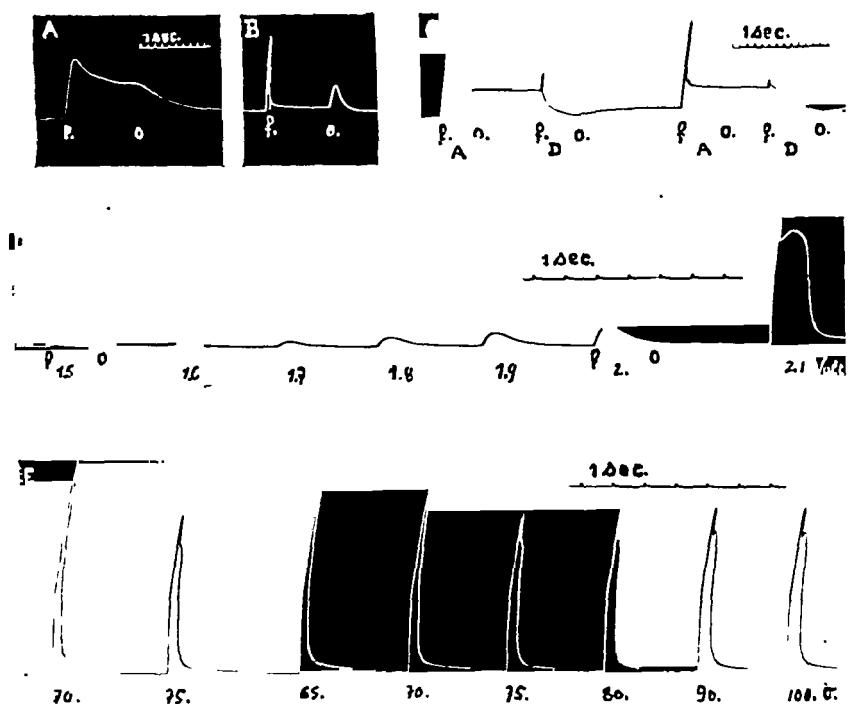

Fig. 18.—Galvanic contractures (galvanotonus) of the gastrocnemius muscle (*in situ*) of normal brown frogs. Direct stimulation of the muscle, either normal (A, B, D and E) or curarized (C) between two electrodes, one at its upper pole, the other at the tendon; f shows the closing; o, the opening of the current. Note that the closing ascending current (cathode proximal) causes much more contracture (A, f) than the descending (B, f) which may even inhibit a preexisting contracture (C, D, f). The opening of the descending current may be contracturing (B, o). D shows that the contracture (slow contraction) may already appear when the strength of the stimulating current is still below its threshold value for the ordinary brief twitch (2.1 volts). E indicates a succession of twitches from the same muscle in answer to galvanic currents all of double the threshold strength for contracture, which was 1.5 volts, but of varying durations. Contracture requires, for each definite intensity of the stimulus, a minimal duration, which is here the chronaxie of the slow contractile mechanism ( $\pm 75$  sigmas at 11.5 C.).

of from 0.4 to 0.7 sigmas for the chronaxie of the ordinary quick mechanism in the same experiments (fig. 18E).

Now, Lapicque and his pupils<sup>33</sup> have shown that whenever there exists between a muscle, or more generally speaking a contractile mechanism, and its motor nerve a marked difference of chronaxie, or a marked heterochronism, this contractile mechanism can be activated only by an adequate repetition (summation) of nerve impulses. The necessity for this summation finds its explanation in the assumption that nerve impulses, which are waves of electrical negativity, stimulate the muscle fibers directly, and when too brief to evoke an answer isolatedly, must be summated, exactly as in these cases brief electrical direct stimuli must be summated.

This explanation of the determinism of neuromuscular contracture accounts very well for its pharmacologic properties, notably for its remarkable elective sensibility to atropine and scopolamine (figs. 15 G, 16 C and D; fig. 17 D). For these alkaloids, being without effect on the contracture of the same muscles determined by direct electrical stimuli, act by an elective curarization of the neuromuscular transmission of the contracting impulses. The possibility of their action being a specific parasympathetic paralysis is immediately excluded by the consideration that the contracting nerve fibers have the same refractory period as the ordinary motor nerve fibers (fig. 12 E and F) and are probably identical with the latter. Moreover, the hypothesis of a parasympathetic innervation of the skeletal muscle fibers has been invalidated by Dale and Gasser.<sup>34</sup> But atropine has been called "the curare of slow muscles."<sup>35</sup> This general property of atropine and allied alkaloids is apparently the reason for their elective action on neuromuscular contracture. It is interesting to see this electivity manifesting itself here, though the two contractile mechanisms are included in the same muscle, and probably in the same muscle fibers.

Fatigue also has an elective curable effect on neuromuscular contracture (fig. 15 A, B and C). A remarkable fact is that a repetition of twitches followed by contracture (fig. 15 A) is more fatiguing than a similar repetition of twitches not followed by contracture (compare fig. 15 A, with fig. 15 B and C).

The action of curare on neuromuscular contracture is much less elective than that of atropine and fatigue (fig. 16 A and B). Epinephrine is without any effect on it.

*Biologic and Physiopathologic Meaning of Neuromuscular Contracture and the Contractile Duality of Skeletal Muscles.*—In spite of its

33. Lapicque (footnote 3). Chauchard: *Compt. rend. Soc. de biol.* **95**:370. 1927.

neuromuscular determinism, the slow contraction described cannot be, for many evident reasons, the physiologic substratum of reflex tonus. Let us recall only its necessary association with phasic contractions, its frequent prolongation in a long lasting contracture, its resistance to curare, its sensibility to atropine and its absence in green frogs.

But neuromuscular contracture gives a clue to two interesting physio-pathologic phenomena.

1. The curious contracture of brown frogs, described several years ago by Riesser and Simonson<sup>34</sup> is a neuromuscular contracture evoked by a summation of nervous impulses reflexly emitted by the nerve centers when in a state of toxic hyperactivity. The Riesser and Simonson contracture has all the myographic and pharmacologic properties of neuromuscular contracture. Contrary to the assumption of its discoverers, it has then no relation to the decerebrate rigidity of mammals. 2. In my experience, normal mammalian muscles do not exhibit neuromuscular contracture. Neither do the rigid muscles of patients with Parkinson's disease. The rigidity is probably a reflex hypertonia (Walshe), and its sensibility to scopolamine may be explained by a central action of the drug.

But the contracture which follows the voluntary contraction in Thomsen's disease and other myotonic conditions, notably myopathies, has such analogies to the neuromuscular contracture of amphibians, that it is not adventurous, in spite of the zoological distance, to conclude that they are fundamentally identical: 1. Both contractures are evoked by a quick succession of nervous impulses. 2. Both are electively sensitive to fatigue. One knows that this elective fatigability of the myotonic contracture, which disappears after a few repetitions of the voluntary movement, allows the myotonic patients to live a nearly normal life. 3. Both contractures are exaggerated by cold. 4. Myotonic muscles<sup>35</sup> exhibit exactly the same aptitude to contracture on galvanic stimulation as the muscles of brown frogs and toads which show neuromuscular contracture, and the myograms of these galvanic contractures are strikingly similar. 5. The duality of chronaxies (a brief normal one and a very great one) which I have found in the muscles of amphibians exhibiting neuromuscular contracture recalls strikingly the chronaxial duality of the myotonic muscles, which has been described by Bourguignon.<sup>36</sup> The values of the great chronaxies in both cases are of the same order. 6. Exactly as in the muscles of amphibians, a minimal frequency of a succession of nervous impulses, or of brief electrical stimuli, is neces-

34. Riesser and Simpson: *Arch. f. d. ges. Physiol.* **202**:221, 1924. Simonson and Engel: *Ibid.* **206**:373, 1924.

35. Huet and Bourguignon: *Arch. d'électricité méd.*, 1913, p. 366.

36. Bourguignon: *La chronaxie chez l'homme*, Paris, Masson & Cie., 1923.

sary in order to evoke a contracture of myotonic muscles in human beings. It remains only to verify the fact, which I hope to do soon, that the electromyograms of the two phenomena are also analogous.

The so-called myotonic contraction of Thomsen's disease and other allied conditions is, then, most probably a neuromuscular contracture, evoked in abnormal muscles by a summation of voluntary nervous impulses normally emitted by the nerve centers, and it has no relation to the mechanism of muscle tone, no more than neuromuscular contracture in amphibians.

When exuberant, as it is often, neuromuscular contracture seems to be a disadvantage rather than of any functional use to frogs, as is certainly the case in the patients with myotonia. But its rapid and elective fatigability and also the fact that the contractile tensions it develops are far from corresponding to the degrees of shortening it may cause isotonically,<sup>37</sup> must greatly limit this disadvantage.

At any rate, the functional significance, if there is any, of the contractile duality of skeletal muscle is obscure. It may be that these properties of the smooth muscles of the normal skeletal muscles of amphibians, reptiles and birds, and of degenerated or diseased muscles of mammals are only a vestigial character, a remnant of their primitive condition, which is also recapitulated in the muscular ontogeny. In the different species of amphibians, and even in different stocks of the same species, the slow contractility, or aptitude to reversible contracture, is unequally developed. Besides it seems to regress during the phylogenetic evolution of vertebrates. In mammals, it reappears only in pathologic conditions of the muscles (wallerian degeneration, myopathy and Thomsen's disease), all characterized histologically by a proliferation of the sarcoplasm and a multiplication of its nuclei.<sup>35</sup>

Besides the physiopathologic facts which it explains, the main interest for the physiologist in the contractile duality of skeletal muscles, and especially in neuromuscular contracture, seems to me that it gives new insight in the problem of neuromuscular transmission. The facts it has revealed, confirming my summation experiments on incompletely curarized neuromuscular preparations,<sup>29</sup> strongly support the Lapicque-Lillie hypothesis that the skeletal muscle fibers are directly excited by the action currents of the nerve fibers, which are probably identical with the nerve impulses themselves.

#### RÉSUMÉ

1. Weak doses of curare have an elective effect on decerebrate rigidity and the reflex hypertonia of local tetanus. The complete or relative integrity of phasic contractility at this early stage of curarization characterized by muscular atonia is shown by the conservation of vigorous

37. Bremer, F.: Unpublished experiments.

bulbar and spinal reflexes. It may be proved by the isotonic recording of the maximal neuromuscular twitch and by the isometric registration of the crossed extensor reflex of the cat. These myograms show the disappearance of the tonic shortening reaction when the contractile phasic tension, or height of the reflex plateau, is still unaffected.

2. Normal (nonexaggerated) reflex tonus is less electively sensitive to curare.

3. This elective effect of curare on tonus, and especially on hypertonias, may be explained by a Wedenski phenomenon: The possibility of the selective blocking of the tonic motor impulses at the curarized neuromuscular junction would be the consequence of their small amplitude, itself a corollary of their particularly high frequency.

These experiments, while they tend to confirm the tetanic nature of the motor innervation of tonus, show that this innervation possesses in its especially high frequency a particularity which may explain its special sensitiveness to different, peripheral or central conditions.

4. The tonus (decerebrate rigidity of cats) abolished at the early stage of curarization may be momentarily restored by the rapid intravenous injection of an appropriate dose of epinephrine hydrochloride. The phenomenon is the expression of a true epinephrine-curare antagonism.

5. The admission of the tetanic nature of tonic innervation does not in itself exclude the possibility of the existence of a contractile duality of the skeletal muscles of vertebrates. The slow secondary contraction described under the name of neuromuscular contracture affords new evidence of the existence of a slow contractile mechanism in the skeletal muscles of amphibians; moreover, it shows the possibility of the activation of this mechanism by nervous impulses.

6. The determining condition of neuromuscular contracture is an appropriate summation of motor nervous impulses.

7. The necessity for this summation is explained by the existence of a considerable heterochronism between the slow contractile mechanism and the ordinary motor fibers.

8. This determinism explains the pharmacologic properties of neuromuscular contracture, especially its elective sensibility to the alkaloids of the atropine group, and to fatigue.

9. The normal functional significance, if there is any, of the contractile duality of the muscles of amphibians (and also reptilians and avians), is obscure. It is not the physiologic substratum of reflex tonus.

10. Neuromuscular contracture, however, explains the centrally conditioned contracture of brown frogs described by Riesser and Simonson.

It has also a striking similitude and is probably homologous to the contracture of Thomsen's disease and other myotonic conditions (myopathy) in human beings.

11. Neuromuscular contracture allows a quantitative study of the phenomenon of summation of impulses and therefore gives an insight into the mechanism of neuromuscular transmission. The results of this study support strongly the theory of the direct stimulation of the skeletal muscle fibers by the action currents of the nerve fibers.

# DEPOSITION OF CALCIUM SALTS IN THE TENDON OF THE SUPRASPINATUS MUSCLE \*

MAXWELL HARBIN

The admirable papers by Codman<sup>1</sup> published in the *Boston Medical and Surgical Journal* on subacromial bursitis have been responsible for a great increase both in interest and in knowledge of the common disabilities of the shoulder girdle. Codman differentiated calcification in the supraspinatus tendon from subacromial bursitis. A review of recent reports, however, indicates that this differentiation is but rarely made and thereby justifies an effort to distinguish further that particular clinical disability which is dependent on a degenerative disease of the supraspinatus tendon, accompanied by the deposition of lime salts but not necessarily with inflammation within the subacromial bursa.

During the early period of more accurate observations on subdeltoid, or better subacromial, bursitis, calcification of the tendon was frequently mistaken for a bursitis, due to the failure to recognize that the area of calcification (fig. 1) rested beneath the inferior wall of the bursa but outside the true shoulder joint.

Prior to 1906 there is little of importance in the literature referable to this disturbance of the shoulder joint, which was often confused by such diagnoses as subacromial bursitis, arthritis, tear of the supraspinatus tendon, dislocation of the long head of the biceps, fracture of the greater tuberosity of the humerus, or, because of the frequency of radiation of pain down the arm, a brachial neuritis.

The most direct mention of a lesion of the supraspinatus tendon as a cause of disability of the shoulder was in a paper by Stevens.<sup>2</sup> It was his impression that either tears of the tendon or an inflammatory process accounted for the disturbance and, contrary to the present concept, he

2. Stevens, J. H.: The Action of the Short Rotators on the Normal Abduction of the Arm, with a Consideration of Their Action in Some Cases of Subacromial Bursitis and Allied Conditions, *Am. J. M. Sc.* **138**:870, 1909.

stated that there was absence of tenderness over the tendon. Previously, in 1906, Dawbarn<sup>3</sup> had described a point of tenderness just above the tuberosity of the humerus, which disappeared under the acromion on extreme abduction, a sign which is rather constant in calcification of the supraspinatus tendon.

In 1907, under a consideration of subdeltoid bursitis, Painter<sup>4</sup> presented x-ray films of five cases, three of which showed definite shadows of increased density over the region of the supraspinatus tendon, unquestionably calcification in the tendon, but described as a thickened bursa; the pathologist, however, reported granules in the

Fig. 1.—Drawing to illustrate the musculotendinous insertions around the shoulder joint, indicating the usual area in which necrosis and calcification occur.

fibrous tissue bordering voluntary muscle fibers. In this paper Painter advocated surgical removal in all cases in which the symptoms persisted over six months.

This disability may be associated with a subacromial bursitis as will be demonstrated in two of the cases to be reported in this article, although it is my impression that it occurs alone more frequently. It would appear that there are two types of calcareous deposit which occur around the shoulder joint: one involving the tendon of the supra-

spinatus alone and the other involving the tendon and the entire sub-acromial bursa; the latter may occasionally contain only a sacculated deposit.

In a series of five cases reported in this article the two cases with associated subacromial bursitis and calcification presented much more acute symptoms than those in which the tendon alone was involved, although it would seem that the patients are just as readily amenable to surgical treatment.

In order for one to have a thorough understanding of this condition, mention should be made of the mechanics of the shoulder joint. It is a true ball and socket joint which embraces two sets of muscles; one connects the shoulder girdle with the trunk and the other the humerus with the shoulder girdle. The inner end of the clavicle articulates with the sternum and gives a bony support to the shoulder girdle at this point. The rest of the shoulder girdle, comprising the remainder of the clavicle and all of the scapula, and bearing the weight of the whole upper extremity, hangs from and is supported and moved by the muscles which pass from it to the vertebrae posteriorly, and to the skull, hyoid bone and ribs anteriorly.

The upper extremity is an organ of prehension and not of support; the shoulder joint, which is the articulation which connects it with the trunk through the shoulder girdle, is constructed with the idea in view of favoring and permitting motion and not of supporting weight or assisting force. The clavicle keeps the joint well out from the side of the body; hence, the neck of the humerus is short. The movements of the arm are so extensive and free that the tuberosities of the humerus do not need to be so large or set so far away from the articular surface as is the case with the femur and its trochanters.

The ligaments of the joints are inelastic tissues; hence, those that enter into the construction of a movable joint must be loose, and the more movable a joint is, the more does its security depend not on its ligaments, but on its muscles.

The muscles have a much more intimate relation to this joint than they have to any other, and this adds to the complexity of the situation. Certain muscles and their tendons pass across the capsule, in some cases blending with it, so that there is the closest relationship between the muscles, the tendons, the capsule and the ligaments. In close relation with the capsule and ligaments, and strengthening them, are the following tendinous structures: above, the supraspinatus; below, the long head of the triceps; behind, the infraspinatus and teres minor; and in front, the tendon of the subcapularis.

In addition to this intimate relation between the tendons and capsular ligament, there are several important bursae in the immediate neighborhood of the joint. The subacromial bursa, between the under surface

of the deltoid muscle and the outer surface of the capsule, consists of two parts, a strictly subacromial portion and a subdeltoid. The base of the bursa is attached to the top of the tuberosity of the humerus and the tendinous expansion of the supraspinatus, and the subdeltoid portion of the bursa, which is movable in its periphery and by moving on itself allows the roof to slide in the base. The bursa is variable in size and somewhat over 6 cm. in diameter. Several other bursae exist around the shoulder joint, but since they do not bear on the present topic will not be discussed.

The deltoid, assisted by the supraspinatus, raises the arm from the side. A consideration of the deltoid and supraspinatus will show that the first action of the deltoid in contracting must be to press the humerus up against the acromion and then to abduct, but that the supraspinatus muscle has only one function, that of abduction. Weakness in abduction, therefore, does not mean that it is necessarily caused by a disease of the deltoid, because soreness or pain in the region of the tendinous insertion of the supraspinatus will greatly limit abduction, and Duchenne<sup>5</sup> has reported a case of circumflex paralysis in which the supraspinatus alone was sufficient to produce abduction of the arm.

Since the function of the rotators of the shoulder has been so thoroughly considered by Stevens,<sup>2</sup> there is little need for recapitulation here.

In those cases in which calcification of the supraspinatus tendon occurs, it is frequently observed that internal rotation and abduction is more painful than external rotation and abduction whether executed actively or passively. This is well illustrated in case 1 in which active abduction in internal rotation was limited to only 35 degrees, whereas with the arm in the position of external rotation, the arm could be carried through its complete range of abduction in a painless manner. An explanation for this phenomenon would seem to be that in the internally rotated position a greater portion of the surface of the supraspinatus tendon must come into contact with the acromion or there is more pressure at this site in this particular position. Impingement of the tuberosity and tendon occurs between 35 and 50 degrees. The failure of the short rotators to perform their function properly may be a factor in the occurrence of this phenomenon in some cases. Stevens has admirably shown how these short rotators of the arm tend to prevent the upward thrust of the humerus caused by the contraction of the abductor muscles.

The etiology of this calcified deposit in the supraspinatus tendon is still largely conjectural; various theories have been advanced, but none

---

5. Duchenne, cited in Lovett, Robert W., and Jones, Robert: *Orthopedic Surgery*, New York, William Wood & Company, 1923.

has been proved. Inflammation, bacterial or toxic, trauma, either frequently repeated, such as may occur from ordinary abduction of the arm with impingement of the tendon against the acromion or by a direct blow on the prominence of the shoulder or a partial or complete tear of the tendon itself with resultant calcification, may act as an etiologic factor. The histories of these patients rarely suggest either of the latter two possibilities so that it would seem they might be excluded as the common cause. In the five cases reported in this article, there was no evidence to suggest tear of the tendon, and Carnatt,<sup>6</sup> in a most excellent consideration of this disturbance, gained the impression following fourteen operations that in none of his cases was it due to rupture of the tendon fibers.

The blood supply to tendons is notoriously poor, and it is probable that frequently repeated mild trauma to the tendon may occur as a result of impingement of the tendon against the inferior surface of the acromion on abduction with resultant necrosis of tendon and calcification.

Evidence of the rapidity with which calcification may occur is cited by Schujenioff<sup>7</sup> who has found lime salt deposited in muscle fibers thirty-six hours after suture of a divided muscle. Moschowitz<sup>8</sup> has advocated the theory of trauma as a cause; he cited three cases of Brickner's<sup>9</sup> in one of which the deposit was noted sixteen days after injury, a second at four months and a third at one and one-half years after injury; unfortunately, however, there is no concrete evidence to show that these deposits did not exist before trauma was inflicted.

Following a searching history, in all of the cases reported in this article, severe trauma could not be elicited as a cause, except possibly in case 5, and even in this instance the patient gave a history of pain in the shoulder antedating the acute injury some two years so that the latter probably served only to accentuate a preexisting disturbance. In those cases in which the subacromial bursa contains the calcified material, one may easily gain the erroneous impression that staphylococcus pus has been encountered because the consistency and color is not unlike the latter, and to make it even more suggestive increased surface heat and fluctuation over the bursa were observed in case 5.

While the associated involvement of the bursa and spinatus tendon has been considered unusual by those who have drawn conclusions from a larger series than this, one is forced to believe that it must not be uncommon since it occurred in two of this small series of five cases. Consequently it is wise to caution that when the bursa is filled with this material, completely or in part, the tendon also may be affected, and unless it is reckoned with, there is a probability that the patient will not gain complete relief.

Although it is unusual, such a suspension of calcified material may be encountered in any bursa; in an unreported case the author observed both olecranon bursae and a bursa of one knee involved; dense shadows were noted in the roentgenogram, and biochemical analysis showed virtually the same composition as that described in case 5, and cultures of the material showed no growth.

#### SYMPTOMS AND SIGNS

The clinical manifestations of calcification of the supraspinatus tendon ordinarily are clearcut. The age incidence has been given little consideration in the literature; it is interesting to note that no cases occurring in children have been reported. The majority of the patients are between 35 and 40 years of age. The onset is usually gradual, and the patient rarely consults the physician early; pain in the region of the apex of the shoulder joint, occasionally radiating down the inner aspect of the arm, is frequently the first symptom. Later there is limitation of motion evidenced especially by inability to place the hand back of the head. Many patients complain of tenderness over the shoulder and state they are unable to lie on the affected part; at times even the pressure of an overcoat is uncomfortable. A few of the patients discovered that by outwardly rotating the arm they can abduct it without pain. Case 1 was one of this group; the patient had volunteered this information to several physicians whom he had consulted, and because of it one orthopedic surgeon had made a diagnosis of relaxation of the capsule of the shoulder joint.

An ache in the region of the joint is common and frequently prompts a diagnosis of arthritis. Many patients have had teeth extracted and tonsils removed without relief, while others have had their shoulders manipulated under anesthesia by overzealous surgeons who believed they could overcome nature's protective phenomenon.

Stiffness is not an uncommon complaint and, when combined with pain of an aching character which may be worse during damp weather, is easily confused with arthritis. Fever is rarely ever present, and the leukocyte count is usually normal. The contour of the shoulder joint shows little change; atrophy of the muscles occurs to a limited degree in the more severe cases, and when the bursa is filled with the calcium

suspension, fulness at the apex of the shoulder may be observed together with fluctuation; tenderness over the entire bursa may be present. In the uncomplicated case when calcification of the tendon alone exists, tenderness is well limited to a point just below the acromial process. Abduction of the arm is limited to a varying degree, and there is usually less pain on abduction in external than internal rotation. Contracture of the inferior portion of the capsule rarely occurs unless there is a superimposed periarthrititis which is the exception rather than the rule.

Especial emphasis should be placed on the proper roentgenologic technic. During the early days of the treatment of patients with this disturbance, as well as too often at the present time, failure to make a diagnosis has resulted from lack of placing the tube at a proper angle to avoid overlapping of shadows. The patient should lie with the arm outwardly rotated, and the x-ray tube placed over the base of the neck and directed outward and downward. The neglect of this technic is well shown in figure 6 which was inserted largely to emphasize this point.

Calcification in the supraspinatus tendon may occur without symptoms, although I have never encountered it; Carnatt,<sup>6</sup> however, has cited several instances.

#### TREATMENT

The management of these patients is largely dependent on whether the condition is chronic or acute. Obviously, when the calcified material is present without causing symptoms, there is little need for treatment and this group need not be considered.

Patients in the chronic group run a self-limited course, and occasionally the condition clears up without treatment. Heat may allay the pain to a degree. While diathermia has been advocated, and certain proponents of its use claim excellent results, as yet no observations made during a follow-up of cases in which the patients were treated in this manner have been published to justify the claims. My limited experience with it has given the impression that no more can be accomplished by the use of diathermia than by the heat obtained from an ordinary electric baker. Massage following the application of heat is helpful, but passive motion and attempts to overcome the muscle resistance is unphysiologic and distinctly harmful since it merely results in increasing the irritability of the part. Active abduction and external rotation is helpful toward overcoming adhesions and can best be carried out by having the patient bend the trunk forward dropping the arms over the head in an attempt to touch the floor with the palms forward.

The conservative treatment in the acute cases seems to me unwise, although if insisted on should be carried out by supporting the arm on a

splint in the maximum position of abduction and outward rotation in which the arm can be placed without production of pain. During this period cold applications are usually more comfortable than heat. Since the operative treatment is so simple, offers so little danger and promises complete relief in practically 90 per cent of the cases, one should have little hesitancy in urging it in all cases in which the condition has persisted over a period of months without relief by the more conservative measures.

The operation itself is relatively simple, and in my practice has been carried out under gas-oxygen-ether anesthesia with the patient resting on the uninvolved side. A linear incision about 12 cm. is made from just above the acromial process downward, the arm resting in external rotation. The deltoid is split in the direction of its fibers; the roof of the bursa is incised and explored. When there is a concurrent bursitis or deposition of the calcific material in the bursa, the wall of this structure is excised. The area of necrosis and calcification can be seen readily, resting just proximal to the greater tuberosity of the humerus. It is advisable to excise this area by sharp dissection through the surrounding normal tendon. Often it is impossible to approximate the tendon edges; neither this denuded surface nor the excision of the bursa seems to prevent a complete return of function in the shoulder joint. The bleeding is usually easily controlled. The deltoid muscle is sutured with plain catgut no. 0, the fascia with interrupted chromic catgut no. 0 and the skin with interrupted silk. A plaster spica of the shoulder is then applied with the arm in external rotation; with one exception the patients in the cases here reported have tolerated this position well. This case had definite periarthrititis of the shoulder with contracture of the capsule, and the operation itself was perhaps ill advised. The plaster spica is removed at the expiration of ten days and baking, gentle massage and active motion are begun.

The majority of these patients experience immediate relief following operation. This is particularly true of those cases in which only the spinatus tendon is involved. The return of function in case 5 unquestionably was delayed by a superimposed traumatic arthritis; however, after a period of four months function was normal and painless.

#### REPORT OF CASES

**CASE 1.—History.**—A white man, aged 42, a stationary engineer, was admitted to the Lakeside Hospital on June 19, 1925, with the complaint of pain, stiffness and locking of the right shoulder. It was first noted one year before when, on using the shoulder, the part felt weak and ached when the arm was abducted. There was no history of trauma. The patient soon found it impossible to raise the arm above the level of the shoulder. He discovered, however, that by a certain manipulation of the joint it was possible to raise his arm above his head. The manipulation seemed to consist in rotating the arm outward before abducting, car-

rying the arm upward in an outwardly rotating position. In spite of physiotherapy, pain and disability became worse. He had had three abscessed teeth extracted, and in January, 1925, removal of the tonsils was carried out in the hope of relieving the pain in the shoulder. His general health had always been excellent, and his history otherwise was unessential.

*Examination.*—On examination he appeared to be a healthy, well developed man whose general examination was unimportant. There was some atrophy of the right shoulder girdle with a point of tenderness just lateral to the acromial process. Passive abduction of the arm adduced pain in the neighborhood of the subacromial bursa. Active abduction could be carried to 45 degrees but with considerable pain. Following rotation of the arm outwardly the patient was able voluntarily to carry the arm over the head. There was no periarticular thickening and no fixation at the shoulder joint. The roentgenogram (fig 2) of the shoulder showed an area

Fig. 2 (case 1).—Diffuse deposition of lime salts proximal to greater tuberosity of humerus.

of increased density about 0.5 cm. in diameter mesial and just above the greater tuberosity of the humerus. It was considered to rest in the substance of the supraspinatus tendon. The urine was normal; the white blood cells numbered 8,500; the hemoglobin content was 90.

*Treatment and Course.*—With the patient under general anesthesia, a linear incision 5 inches (12.7 cm.) in length was made from just above the acromial process downward, exposing the deltoid muscle which was split in the direction of its fibers. The subacromial bursa showed no thickening of the walls. There were a few adhesions in the superior portion. When the arm was adducted an area of necrosed tissue was seen at a point just above the tuberosity of the humerus, which was infiltrated with whitish, gritty material apparently containing lime salts. This area was about 1.5 cm. in diameter. This rested in the substance of the supraspinatus tendon. It was completely excised. The free tendon edges could not be sutured. The deltoid muscle was approximated with interrupted sutures of plain

catgut no. 0, the fascia with interrupted sutures of chromic catgut no. 0 and the skin with silk. The arm was put up in a plaster spica in 90 degrees abduction and 75 degrees outward rotation.

*Pathologic Report.*—The specimen consisted of a small mass of densely fibrous tissue which on palpation was found to contain irregular patchy areas of stony consistency. The material was cut with great difficulty; there was a considerable amount of hard granular material throughout. One end of the specimen showed what appeared to be a few strands of muscle interspersed with the fibrous connective tissue.

The tissue was made up for the most part of dense fibrous connective tissue showing extensive hyalinization, and in one of the sections there were a number of bundles of striate muscle. These bundles were separated from one another by dense fibrous connective tissue trabeculae. In the purely fibrous portion of the specimen two types of nuclei were seen. The nuclei were predominantly elongated and spindle-shaped, but in several areas they were round and situated in large cells with distinct cell outlines which were distributed in small groups of two or three. It was in the vicinity of these groups of cartilage cells that the granular calcific depositions were seen.

The maximum postoperative rise of temperature occurred on the second day, reaching 38 C. (100 F.), with a gradual return to normal. The plaster splint and the sutures were removed on the eighth postoperative day. The wound had healed nicely. Physiotherapy was begun. The patient was discharged from the hospital on June 30, 1925.

A follow-up note from the patient one month after discharge stated that he had a complete return of function in the right arm, had assumed his regular work and had noted no pain since operation. A letter from the patient in June, 1926, stated "I haven't an ache or pain in my shoulder or arm and would not know I ever had except for the scar." Examination a few months later showed normal function of the shoulder joint.

This perhaps is one of the most typical cases. The patient had the experience of losing both teeth and tonsils under the impression that the pain in the shoulder was of arthritic origin and because of the discovery that by voluntary manipulation of the shoulder into outward rotation the part could be abducted painlessly, he had been advised that the joint capsule was relaxed. The roentgenogram (fig. 2) showed a diffuse shadow, and the bursa itself was essentially normal. At the end of one month there was complete return of function, and he had resumed his former occupation, following a period of one year's disability.

*CASE 2.—History.*—A Croatian, a steel worker, aged 38, was admitted to the Lakeside Hospital on Jan. 18, 1926, with the complaint of pain in the right shoulder which had been present for about two and one-half years. The onset was rather insidious and associated with no trauma. The pain was of an aching character and had grown progressively worse with occasional exacerbations of sharp pain on abduction, several times radiating down the volar aspect of the forearm. He had noted the pain was worse on active abduction of the arm as contrasted with passive motion. The disability reached a point where it was impossible at the time of entrance to place the hand back of the head. It also kept him awake at night, particularly if he lay on the right shoulder, and in the morn-

ings on getting up he was unable to make a fist with the right hand. He had had physiotherapy for a period of several weeks without relief. The patient felt the sensation of "something catching in his shoulder joint" on forced abduction. He had been coming to the dispensary since the onset of his illness, and a roentgenogram taken in 1924 showed what was considered calcification in the subacromial bursa.

*Examination.*—The examination showed a well developed white man and was unimportant except for the local disturbance which presented moderate atrophy of the shoulder girdle with a point of tenderness just below the acromial process<sup>10</sup>

Fig. 3 (case 2).—Discrete shadow of lime salt in supraspinatus tendon easily confused with fracture of the greater tuberosity of the humerus.

which disappeared on abduction. Active abduction of the arm was possible to 90 degrees, but there was considerable pain in the shoulder on attempting to carry the arm past this point. Backward and internal rotation produced considerable pain. There was no swelling or redness over the joint. The roentgenogram (fig. 3) showed a shadow of increased density about 0.5 cm. in diameter lying above and just medial to the greater tuberosity. The urine on three examinations was normal. The white blood cells numbered 7,000; the hemoglobin was 90.

10. Dawbarn's sign.

*Treatment and Course.*—With the patient resting on the left side and under general anesthesia, following the usual preparation of the skin, a linear incision was made over the apex of the shoulder and was carried through the skin and deltoid fascia. The fibers of the deltoid were separated, exposing the roof of the subdeltoid bursa. This portion of the bursal wall appeared to be normal. There was an area of necrosis in the region of the supraspinatus tendon which contained a few drops of creamy material which looked not unlike staphylococcus pus. Cultures were taken as well as smears. The cultures were negative. The smears showed no organisms. The deposit was about 2 cm. in diameter. It was dissected completely from the bed. The bursal wall was sutured with interrupted silk, and interrupted silk was used to approximate the fascia of the deltoid and the skin. The arm was placed in a plaster spica in a position of 90 degrees abduction and 70 degrees outward rotation. The patient made a normal postoperative convalescence; the maximum temperature was 38 C. (100 F.). The sutures and plaster splint were removed at the end of one week, and physiotherapy was begun. The patient was discharged from the hospital on Jan. 31, 1926, to be seen later in the follow-up clinic.

*Pathologic Report.*—The pathologic observations were essentially identical with those reported in case 1.

In April, 1926, the patient still complained of some pain in the shoulder on doing hard work, although for ordinary purposes it caused him no trouble. In June, 1927, examination of the shoulder demonstrated normal function without discomfort, although the patient still complained of some stiffness of the fingers in the mornings.

This patient presented very much the same picture as that in case 1 except for a period of two and one-half years during which he had had pain in the shoulder; the shadow in the roentgenogram (fig. 3) was more discrete and might easily have been mistaken for a fracture of the tuberosity of the humerus. Return of function was somewhat more prolonged, and discomfort did not entirely disappear until seventeen months after operation.

*CASE 3.—History.*—A white married man, aged 55, a salesman, was admitted to the Lakeside Hospital on July 28, 1927, with the complaint of pain in the right shoulder. About twelve years before, the diagnosis of diabetes had been made, and the patient had been on a rather restricted diet since that time. One year before, without any apparent injury he suddenly began to note pain over the region of the right shoulder which was aggravated by exercise. This pain was sharp in character and radiated to the lateral elbow. He gained temporary relief by heat during the early days following the onset. Eight months before admission, he wore a sling for several weeks with some relief but noted during this time increase in stiffness. Diathermia was tried for a few weeks without relief. Recently, he had consulted an osteopath and had been seen by an orthopedic surgeon. The latter had advised an ether manipulation of the shoulder. The pain had been worse before admission.

The past history was unimportant except for the diabetic disturbance. An occasional urinalysis had shown 0.5 per cent of sugar. During the past forty years he had had some aching in the legs with changes in the weather.

*Examination.*—Examination showed a well developed man. There was considerable pigmentation of the right arm and shoulder, the result of exposure to the

ultraviolet lamp, with slight atrophy of the shoulder girdle. There was considerable pain to pressure just below the acromial process. Abduction of the shoulder was painful beyond 30 degrees with complete limitation beyond this point. External rotation was restricted to 40 degrees, and internal rotation was limited to 25 degrees. Scapular abduction was limited to 45 degrees. Abduction and internal rotation of the arm produced a greater amount of pain than abduction and external rotation. A roentgenogram (fig. 4) of the shoulder showed an area of increased density just above the tuberosity of the humerus which suggested calcification of the supraspinatus process. The blood pressure was systolic 135 and diastolic 90.

Fig. 4 (case 3).—Diffuse calcification in the musculotendinous portion of the supraspinatus tendon.

The blood sugar was 11.7 per cent. The urine showed 0.7 per cent sugar but was otherwise normal. The white blood cells numbered 7,900. In view of the fact that the patient was diabetic, it was deemed wise to explore the supraspinatus tendon under anesthesia with procaine hydrochloride.

*Treatment and Course.*—With the patient lying on the left side, the skin was prepared in the usual manner, and a linear incision 5 inches (12.7 cm.) in length was made over the apex of the shoulder from the acromial process downward. The roof of the bursa on incision showed the sac to be obliterated. The walls were definitely thickened and hyperemic so that the supraspinatus tendon did not

possess its usual whitish appearance. During a search for about one hour it was impossible to identify the suspected deposition of lime salt. In view of this negative observation a small incision was made into the capsule of the shoulder, and the joint was explored. No loose body could be found. A section of the supraspinatus tendon was removed at a point where the x-ray picture suggested there was a deposition of calcified material. This tendon showed definite fatty degeneration in the tendon but no granules. The small opening in the capsule was closed with interrupted sutures of chromic catgut no. 0. The supraspinatus tendon was sutured with the same material. A portion of the wall of the subacromial bursa was excised. The fascia was sutured with interrupted sutures of chromic catgut no. 1, and silk sutures were used in the skin. Because of the resistance of the arm to abduction with the local anesthesia, gas-oxygen was administered with entire relaxation. It was impossible to abduct the arm beyond 80 degrees due apparently to contracture of the inferior capsule as well as of the pectoralis muscle. The arm was placed in abduction on an airplane splint, and the patient was sent to the ward in good condition.

*Pathologic Report.*—The specimen consisted of a small irregular fragment of muscle and tendon. There was no evidence of calcification, nor was any abnormality noted on microscopic examination.

The patient made a rather uncomfortable convalescence during the first three or four days after operation. Physiotherapy was begun at the end of one week. Roentgenograms were taken following the operation and showed partial disappearance of the shadow previously seen in the supraspinatus tendon. The patient was discharged on Aug. 7, 1927, to continue with physiotherapy.

On Oct. 13, 1927, the patient stated that he had returned to his work, that he was able to drive his car and that it was also possible for him to place the right hand behind the head. Previous to the operation he had been unable to do either one. There was a range of 45 degrees abduction free of the scapula with a limitation of 35 degrees to internal and external rotation. The limitation of motion seemed to be due to contraction of the capsule and pectoralis muscle; one could not be sure about the subscapularis. He still complained of some stiffness of the shoulder on getting up in the morning. It would seem that periarthrits played a great part in the production of his disability as well as the thickened bursa. It is unfortunate that the bursa was not completely removed. The operation as performed probably accomplished little.

Nowhere in the literature has any one suggested any relationship between the relation of calcification of the spinatus tendon and diabetes, and the occurrence in this patient is probably only coincidental. The pain had persisted for one year prior to the patient's entry to this hospital, although he had suffered with aching in various joints during atmospheric changes for forty years. The roentgenogram (fig. 4) showed a definite shadow in the region of the supraspinatus tendon, although at operation no necrosis or calcification could be found following a thorough search which included exploration of the joint itself. The bursal sac was definitely thickened and hyperemic but unfortunately was not excised. Contracture of the inferior capsule of the joint complicated the picture. The patient made a rather uncomfortable convalescence, but at the expiration of three months he was able to return to his work with much less pain and definitely improved function.

A postoperative roentgenogram at three weeks showed a diminution in the area of calcification, although the pathologist failed to find calcific material in the sections.

*CASE 4.—History.*—A white man, aged 42, a laborer, was admitted to the Lakeside Hospital on April 17, 1928, with the complaint of pain in the left shoulder. He stated that seven years before he first noted an aching pain in the region of the left shoulder. This pain steadily grew worse until it became sharp in character; it was localized to the region of the subacromial bursa and occasionally radiated down the outer arm to the elbow. He had noted increasing stiffness up to the time of admission. Two years before, because of the severity of the pain, several hypodermic injections of morphine had been given. Four teeth were

Fig. 5 (case 4).—The subacromial bursa distended with calcium salts in suspension beneath which is a second shadow representing deposition of lime salts in the tendon of the supraspinatus muscle.

extracted at that time without producing relief. The pain had usually been worse during the evening and also definitely worse with changes in the weather. One week before the patient was admitted to the hospital the pain had become so severe that he was forced to give up his work as a street laborer. The past history was relatively unimportant, except for a mass descending occasionally into the left scrotum which he had always been able to reduce.

*Examination.*—Examination showed a well developed laborer. He had considerable dental caries; there were several crowned teeth. There was an impulse in the left inguinal ring on coughing. The left shoulder girdle showed moderate atrophy with an area of fulness and increased surface heat over the region of the subacromial bursa. It was fluctuant in character and tender on deep pressure. The arm could not be abducted beyond 45 degrees without the production of

considerable pain. Inward rotation and abduction was distinctly more painful than outward rotation and abduction. The roentgenograms (figs. 5 and 6) of the shoulder showed an area of increased density conforming to the subacromial bursa, with a second shadow of irregular density below the former shadow and in the neighborhood of the supraspinatus tendon. Roentgenograms of the teeth showed one alveolar abscess. The urine was normal. The white blood cells numbered 10,900. The Wassermann reaction was negative.

*Treatment and Course.*—With the patient resting on the left side and under general anesthesia a linear incision 5 inches (12.7 cm.) in length was made from

Fig. 6 (case 4).—Roentgenogram made at the same time as figure 4, illustrating failure to show shadows in the bursa and tendon due to improper roentgenologic technic.

the region of the acromial process downward. The deltoid was split in the direction of its fibers exposing the roof of the bursa. This appeared to be thickened and fluctuant, and on incision a thick, white, nontenacious fluid came away under some pressure. Two swabs of material were sent for examination, and cultures showed no growth in forty-eight hours; a smear showed no organisms or cells. Unfortunately none of the fluid was collected for biochemical study. The bursal wall throughout was thickened and hyperemic and bled considerably. It was completely excised. On inspecting the supraspinatus tendon there was an area of necrosis 5 by 10 mm. in diameter. This was fibrillated and contained many

soft granules. Complete excision was carried out. The true joint was not entered. It was impossible to approximate the supraspinatus tendon. The deltoid muscle and fascia were closed with interrupted sutures of chromic catgut no. 1, the subcutaneous tissues with plain catgut no. 00 and the skin with silk. A small rubber tissue drain was placed in the wound for forty-eight hours. The shoulder was placed in a plaster spica in 90 degrees abduction and 75 degrees external rotation. The patient made a normal postoperative convalescence. The maximum temperature occurred on the second postoperative day, 38.2 C. (100.7 F.). The splint and sutures were removed on the eighth day, and physiotherapy was begun.

*Pathologic Report.*—The specimen consisted of several varying sized fragments of dense fibrous connective tissue which were cut with great difficulty; distributed throughout the specimens were small, irregular collections of what appeared to be a soapy, granular, white material. In the vicinity of these deposits the tissue was particularly dense and elastic.

There was extensive hyalinization of the fibrous connective tissue, and in many areas small groups of cartilage cells were seen to be distributed throughout the hyaline matrix. In this hyaline matrix there were large areas occupied by a dark blue staining homogeneous material which resembled mucoid degeneration of cartilage rather than calcification. This process appeared to have replaced large areas of the tissue rather than to have infiltrated it. In no place did it have the fine granular appearance of beginning calcium deposition in cartilage.

Two weeks following the operation on the shoulder, a herniorrhaphy was also carried out, and the patient was discharged on May 16 to continue with treatment in the physiotherapy department.

On Aug. 4, 1928, the patient reported to the dispensary and stated that he had returned to his former work and that he experienced no pain in the shoulder. There was a normal range of painless motion in all directions. The result was excellent.

This case instances a long period of pain in the region of the shoulder dating seven years with exacerbations of acute pain necessitating the administration of a narcotic for relief. He also had had teeth extracted without improvement. There was fluctuation over the bursa with increased surface heat, and the roentgenogram (fig. 5) showed the bursa injected with an opaque material and a secondary shadow of increased density in the region of the tendon. The calcific material in the bursa was not unlike staphylococcus pus in appearance. A roentgenogram (fig. 6) taken with the arm internally rotated and the tube placed above the shoulder illustrates how the picture can be confused and instances a possible fallacy that these deposits may make a sudden disappearance. There was immediate relief following operation and an early return of function, although the repair of a hernia delayed the patient's return to work.

CASE 5.—*History.*—A married white woman, aged 34 years, was admitted to the Lakeside Hospital on May 18, 1928, with the complaint of pain in the right shoulder. The immediate reason for entry to the hospital was the result of an automobile accident three weeks before. The car turned completely over; the patient attempted to break the fall by holding to the door with her right hand. For two days following the accident she was not troubled severely, but after this

motion in the right shoulder became so painful that the arm could not be used. She had suffered, however, with pain in this shoulder for about two years, first noted by "locking" at times when she attempted to raise the arm; motion was stopped by pain. She described the pain as like a clamp, and at certain times she found it impossible to put the hand behind her head. She could not lie on the affected shoulder. During all this period she had had no treatment. Two days following the automobile accident she noted swelling and tenderness over the shoulder. The former subsided after about one week, but the pain and tenderness persisted.

Fig. 7 (case 5).—Diffuse deposition of lime salts in supraspinatus tendon.

*Examination.*—Examination revealed a well developed woman, whose general examination was rather unimportant. There was slight thickening over the superior portion of the shoulder with some tenderness to pressure below the acromial process. Abduction was limited to 5 degrees; with scapular motion, abduction could not be carried beyond 60 degrees. External rotation was limited to 20 degrees. On the dorsum of the right wrist there was a fluctuant swelling about 2 cm. in diameter, obviously a so-called ganglion. The urine on three examinations was normal; the white blood cells numbered 7,400; the hemoglobin content was 90. Stereoscopic films (fig. 7) of the right shoulder showed an area of calcification in the neighborhood of the supraspinatus tendon located just above the greater tuberosity. It was considered that the calcification had probably

existed in the supraspinatus tendon for some time previous to the automobile accident, but that the accident had probably superimposed a subacromial bursitis on the previous disturbance in the tendon.

*Treatment and Course.*—Under general anesthesia with the patient resting on the left side the ganglion was excised through a 2 inch (5.08 cm.) incision. A second linear incision about 5 inches (12.7 cm.) in length was then made over the apex of the shoulder, and carried down to the deltoid muscle which was split in the direction of its fibers, exposing the roof of the bursa which was somewhat hyperemic. On incision into the bursa it was found partially obliterated with several small organized hematomas. Just proximal to the insertion of the supraspinatus tendon was an area of yellowish, granular material with necrosis of the tendon. In a small pocket on the inferior mesial aspect of the bursa were a few drops of yellowish, thick, pasty material. The bursal wall was excised as well as an area about 8 mm. in diameter from the supraspinatus tendon. The tendon was sutured with interrupted sutures of chromic catgut no. 0, the deltoid muscle and fascia with interrupted sutures of chromic catgut no. 0 and silk was used in the skin. The shoulder was put up in a plaster spica at 90 degrees abduction and outward rotation. Cultures from the bursa showed no growth in seventy-two hours.

*Pathologic Report.*—The observations were essentially identical with those described in case 4.

The patient made a normal postoperative convalescence. The maximum rise of temperature occurred on the third day, reaching 38 C. (100 F.). She was somewhat more uncomfortable than most of the patients and complained frequently of some pain in the shoulder joint. The splint and sutures were removed on the ninth postoperative day. The wound was clean and firmly healed. Physiotherapy was begun.

The patient was discharged on June 11, 1928, to continue physiotherapy. She did not regain motion so rapidly as usual, and on June 25 was readmitted to the hospital for manipulation under a general anesthesia. At this time definite adhesions could be felt to tear free. The arm was kept in abduction for several days and physiotherapy was resumed.

Unquestionably, the delay in recovery of this patient was the result of the automobile accident which was undoubtedly superimposed on the previously calcified supraspinatus tendon.

On Sept. 21, 1928, function in the shoulder had returned to normal with only slight aching during damp weather.

Here again the patient had suffered from pain in the shoulder for a period of two years and was driven to the hospital by an acute exacerbation following the trauma due to an automobile accident three weeks before entry. There was marked limitation of motion at the shoulder and the roentgenogram (fig. 7) presented a diffuse dense shadow over the region of the tendon. The bursa was partially obliterated, hyperemic with a few scattered sacculated areas of calcific suspension. The bursa, as well as the necrosed tendon (fig. 8), was excised. It is of interest to note the considerable variety of earthy substances which exist in the necrosed tendon. Inorganic phosphates were present to a considerable degree. Calcium was easily discernible with a trace of calcium, iron,

Fig. 8 (case 5).—Photomicrograph illustrating extensive hyalinization of fibrous tissue with groups of cartilage cells distributed throughout hyaline matrix. Calcium containing material is shown in the upper left portion.

carbonates and chlorides. The specimen was composed of tough, white fibrous substance covered in certain areas by a cream-colored cheesy substance. A few gritlike particles were found in the cheesy material. Some hardened blood was present. Analysis of tissue removed from the supraspinatus tendon showed the following:

Fats . . . . .	considerable
Cholesterol . . . . .	positive test (small amount)
Cheesy Substance	
Xanthoproteic . . . . .	+
(after extraction with ether, a white chalky substance remained)	
Biuret . . . . .	+
Millons . . . . .	+
Hopkins Cole . . . . .	slight
Extracted with Warm Diluted Nitric Acid	
Inorganic phosphates . . . . .	considerable
Chlorides . . . . .	.....trace
Extracted with Warm Diluted Hydrochloric Acid	
Calcium . . . . .	present
Magnesium . . . . .	..trace
Iron ....	..trace
Carbonates . . . . .	..trace
Sulphates . . . . .	..none

The white fibrous substance was apparently dense fibrous connective tissue. The yellow cheesy substance was composed of fat, protein and a fair amount of calcium phosphate.

The return of function was somewhat slow but was complete at about three months. There is some doubt as to the wisdom of excision of the bursa when it is involved with the tendon; this point has not been given sufficient study, although with the present knowledge excision is probably advisable.

## CONCLUSION

A degenerative disease of the musculotendinous portion of the supraspinatus tendon with deposition of lime salt is considered. The fact that this may occur in conjunction with a subacromial bursa impregnated with the same salts as are seen in the tendon is also emphasized. The etiology has never been definitely established, inflammation, bacterial or toxic, or trauma have been suggested. In none of the five cases reported in this paper could external injury be considered as a cause; frequently repeated mild trauma to the tendon occurring as a result of impingement of the tendon against the inferior surface of the acromion seemed most probable.

The anatomy and mechanics of the shoulder joint are briefly related. The clinical course and treatment are outlined, and five cases are reported in detail. Emphasis is placed on the concomitant incidence of involvement of the spinatus tendon and bursa. When the bursa is affected, a thorough exploration of the tendon for deposit of lime salt should be instituted and both the bursa and diseased tendinous portion excised.

The good results of surgical treatment in cases uncomplicated by arthritis are demonstrated.

### INTRODUCTION AND CLASSIFICATION

Disagreement and controversy regarding the etiology, classification and diagnosis of malignant tumors of the lymph nodes make their study a subject of interest and importance. My aim in this paper is to present clinical data and basic facts gained from a study of forty-one patients personally observed at the Steiner Clinic from 1924 to 1928, inclusive. Only those cases in which the diagnosis was proved by biopsy or necropsy have been considered, although twenty others in which a probable diagnosis of malignant lymphoma was made were observed during the same period.

Numerous classifications have added to the complexities of the subject and to the difficulties of the clinician and the pathologist. For this reason, only the frequently occurring types will be discussed. Certain transitional forms occur which add to the difficulties of accurate grouping, and for this reason some pathologists class all such tumors under the broad term lymphoblastoma, believing that all are but manifestations of the same process. However, it is thought that the patients concerned in this study present definite clinical and pathologic pictures by which they can be accurately classified. Anatomic classification, depending on the histogenesis, as advocated by Ewing, seems the simplest and most logical since a lack of knowledge precludes classification according to the etiologic factors. Table 1 shows the tumors here studied classified according to Ewing:

For the sake of simplicity, the two types of leukemia are considered singly, as are Hodgkin's disease and Hodgkin's sarcoma. For the same reason, large-cell lymphosarcoma (reticulum cell sarcoma) and malignant lymphocytoma are grouped clinically as lymphosarcoma.

---

\* From the Department of Surgery, Steiner Clinic, Atlanta, Ga.

The neoplastic growths of lymphoid tissue which will be considered are: (1) lymphatic and myelogenous leukemia; (2) Hodgkin's disease; (3) lymphosarcoma, and (4) endothelioma.

### LEUKEMIA

Of all the diseases of the blood-forming organs or of the lymph nodes, leukemia presents the most striking picture because in it the blood is flooded with a large number of abnormal cells, which differentiate it from other similar neoplasms. The type of cell which predominates is of more importance than the number of the cells present, and on this depends the classification of the disease. Thus, in myelogenous leukemia, the myelocyte makes up from 15 to 70 per cent of the leukocytes, while in acute lymphatic leukemia the large immature lymphocyte is the predominating cell. In the chronic type of lymphatic leukemia, the small lymphocytes are most abundant.

From tables 2 and 3 it would appear that the myelogenous form occurred with about the same frequency as the lymphatic variety. As

TABLE 1.—*Classification of Tumors*

Origin	Anatomic Type	Clinical Type
Lymphocytes	Lymphocytoma	Lymphatic leukemia Malignant lymphocytoma
Reticulum cells	Large round cell hyperplasia	Hodgkin's sarcoma Myelogenous leukemia
Endothelial cells	Endothelial hyperplasia	.

has been noted in other studies, it occurs more frequently in males in the ratio of 2:1. It would be supposed that leukemia would occur more frequently in early youth when blood-forming organs were active, but in this series the average age is about 40, and in three patients the disease began after 50 and in one at 70 years of age. The age of the patient is therefore of little if any value in differentiating leukemia from other enlargements of the lymph nodes.

*Pathology.*—The nodes are enlarged and fused by an inflammatory reaction. While they may reach considerable size, it is not common to see the large masses that are found in Hodgkin's disease and in lymphosarcoma. There is an obliteration of the normal structure, which is replaced by a diffuse growth of lymphoid cells, the large type predominating in the acute cases and the small cells in the chronic cases. In myelogenous leukemia the normal structure of the lymph nodes as well as the spleen is replaced by cells of the myelocytic series. Secondary deposits in the liver and kidney are found chiefly in the capillaries, and there is no actual destruction of tissue except by compression and atrophy. In the bone marrow, there is a widespread overgrowth of hyperplastic cells.

*Myelogenous Type.*—The myelogenous type of leukemia is usually gradual and insidious in onset. The first symptoms noted are a progressive loss of weight and strength or abdominal pain from enlargement of the spleen. Later, the nodes in the neck and groin enlarge, and a marked anemia is noted. Occasionally there is hemorrhage from the nose, gums or kidneys, but this symptom occurred in only two cases of this series.

The disease rarely runs an extremely acute course in which hemorrhages are extensive. An example of this type follows:

CASE 2286.—A man, aged 21, entered the Steiner Clinic on July 7, 1928, complaining of pain in the back and frequent attacks of profuse bleeding from the

2001	F	19	Enlarged nodes	+	Cervical	3,000,000	31,000	90% small	3 mo.

nose of one month's duration. Nothing abnormal was noted on physical examination, except a pronounced anemia. Examination of the blood showed 3,000,000 red blood cells and 146,000 leukocytes, 40 per cent of which were myelocytes. Roentgen treatment to the spleen reduced the leukocyte count to 48,000, but the anemia increased and the red count fell to 2,000,000. The patient grew rapidly weaker, and died six weeks after entrance to the clinic.

The usual course of myelogenous leukemia is more chronic than that in the foregoing case. Of the eight cases studied the average duration of life after the onset of the disease was twenty-four months, and one patient lived four years. Two patients are living; one ten months and another twenty-four months after the first symptoms.

The leukocyte count in the eight cases ranged from 128,000 to 848,000, 12 to 61 per cent of which were myelocytes. The patient with

the highest leukocyte count is still living two years after the onset, whereas the patient with the acute type, who lived only two months, had a count of 146,000. This would lead to the belief that a high leukocyte count is not evidence of a bad prognosis but is probably an indication of chronicity. The percentage of myelocytes seems to have little bearing on the prognosis, although in the patient living two years the percentage was 61.

As in other malignant diseases, the age of the patient seems to have a direct bearing on the prognosis, for the older the patient the more chronic is the course of the disease.

*Acute Lymphatic Type.*—As in myelogenous leukemia, the course of the lymphatic variety is extremely variable, not only in the rapidity of the disease but in the structures involved and in the character and number of the leukocytes.

In the acute form the symptoms are intense from the start and are usually initiated with fever, weakness, rapid prostration and hemorrhages. Usually one chain of lymph nodes is found enlarged with the onset of symptoms, and this enlargement rapidly spreads to other locations, and frequently to all lymphatic tissue. As a rule the spleen is enlarged but not to the size seen in myelogenous leukemia. Ulceration with hemorrhage occurs in the mouth and throughout the gastrointestinal tract, and hemorrhage of the retina is frequent.

There is usually an extensive but variable increase in the leukocytes circulating in the blood, together with a marked and progressive anemia. The large undifferentiated lymphocytes constitute from 60 to 99 per cent of the total white cells, but may vary both in number and in form during the course of the disease. This type is well illustrated by the following case:

CASE 3702.—A boy, aged 10 years, entered the Steiner Clinic on Oct. 19, 1928, because of a swelling in the left side of the neck (fig. 1). The first symptom was painful deglutition of six weeks' standing, and examination showed the left tonsil to be enlarged and ulcerated. The blood at that time showed 3,900,000 red blood cells and 12,000 white blood cells, of which 55 per cent were neutrophils, 24 per cent small lymphocytes and 8 per cent large lymphocytes. Organisms of Vincent's angina were found in the throat; the patient had been treated for this for two weeks before entrance to the clinic. During this time his general condition grew rapidly worse; he lost weight and strength, and enlargement of the lymph nodes was noted in the left axilla. Roentgen therapy was given to the left side of the neck on Nov. 2, 1928, and four days later the white blood cells numbered 22,000, of which 44 per cent were atypical lymphoblasts with some myelocytes. The treatment by irradiation apparently did not cause any improvement, for the patient grew rapidly weaker. On Nov. 11, 1928, the white cells numbered 82,000, of which 93 per cent were large lymphocytes. The following day the patient died, and the tonsil and nodes of the neck were examined. Both were made up of diffuse mass of large rounded cells which were hyperchromatic and consisted chiefly of nuclei with little cytoplasm.

From the microscopic section and the final blood picture this case was classed as acute lymphatic leukemia, although in the beginning the blood count was normal and later myelocytes appeared in the blood. It is cited as an example of the degree in which the blood picture may change and is an example of the variability of the proportion of lymphocytes. As has been stated, the diagnosis depends not so much on the number of lymphocytes as on their form.

*Chronic Lymphatic Type.*—The chronic type is differentiated from the acute in that the symptoms are less severe, the course more prolonged, and the lymphocytes circulating in the blood are smaller. The onset is gradual, and the first complaint is usually the discovery of

Fig. 1.—Acute lymphatic leukemia. The only evidence of the disease was in the left tonsil and in the left cervical nodes. Roentgen therapy did not cause improvement and was possibly harmful.

enlarged painless nodes. Any group of nodes may be the first to enlarge, but usually other chains are involved and the spleen and liver gradually increase in size. Embolic lymphocytic infiltrations appear in various parts of the body, and the skin, brain and even the heart muscle may be affected.

The disease runs a chronic course, and the nodes continue to enlarge but may be reduced by roentgen treatments. Of the four patients studied in this series one is alive one year after the onset, one, two years and one, four years. The fourth patient died three months after the onset, but the condition was complicated by pregnancy which probably

affected the course of the process. This patient was placed in the chronic lymphatic group because of the blood picture.

It is on the changes in the blood that the diagnosis is established. There is present from the start a moderate anemia which is progressive. The lymphocytes are small and may be greatly increased in number.

*Prognosis and Therapy.*—The prognosis in all types of leukemia is generally bad, but in the chronic forms life may be prolonged for a number of years. From a study of these patients, it is felt that the prognosis is definitely influenced by roentgen therapy. In the myelogenous type, irradiation was given to the spleen, long bones and the enlarged lymph nodes. The dosage was dependent on the response in leukocyte and red blood cell count. In the lymphatic types, the enlarged nodes were treated. While control cases in which treatment was not given were not followed, it is believed that in the chronic varieties life was prolonged and that definite improvement in symptoms was produced.

In the acute cases, response to irradiation is rapid but usually unfavorable. While the leukocyte count may drop rapidly the anemia is likewise greatly accentuated, and it is believed that death is hastened. If such treatment is to be instituted, it should be given carefully and in small dosage to determine the response before more active irradiation is given.

Improvement in clinical symptoms after treatment is noted by a gain in weight and strength. The appetite increases, and the spleen, which causes the pain on account of its enlargement, is reduced in size. Improvement, however, is usually transitory, and a return of unfavorable symptoms occurs. This return can usually be favorably affected by repeated treatments, but as a rule the time comes when resistance to irradiation supervenes and treatment loses its effect.

A complete blood count should be made before each treatment, since a fall in leukocyte count is the best indication to the response to therapy. At the same time, the anemia may be increased if too vigorous irradiation is carried out. Likewise, a too rapid decrease in the white count is accompanied by weakness, and the treatments should be regulated to prevent this sudden change. In fact, it has been frequently noticed that the most favorable response in the symptoms is obtained when the count is reduced to about one fourth of the maximum number of cells.<sup>1</sup>

---

1. The same technic for deep roentgen therapy was used in all cases of this series, except for the factors of time and size of the port of entry. The voltage was 200 kilovolts. The skin target distance was 50 cm., and the filter used was 0.5 mm. of copper and 1 mm. of aluminum. The skin dosage with these factors and a port of 10 by 10 cm. was seventy minutes.

## HODGKIN'S DISEASE

Only those cases in which the typical microscopic picture of Hodgkin's disease as described below was present have been classed under this heading. Indefinite forms of lymphoid hyperplasia, so-called pseudoleukemia and atypical tuberculosis have been discarded. Those patients running the typical clinical course of Hodgkin's disease, but in whom the pathologic diagnosis was questionable, have been likewise excluded. This has been done in order to attempt to draw conclusions from unquestionable cases. Since the etiology is unknown, this anatomic diagnosis seems the only logical means of classification.

Fig. 2.—Hodgkin's disease. Microscopic section in average case, showing lymphocytes, reticulum cells, endothelial cells and giant cells. Moderate fibrosis.

*Pathology.*—The nodes are moderately or markedly enlarged, and while they may appear to be fused during life, the capsules are not invaded and are actually slightly separated. Early in the disease, cross-section of the nodes shows a semitranslucent surface with small areas of necrosis. Later, small hemorrhages appear, and the structure becomes darker in color. Marked fibrosis occurs late in the disease but is usually present to some extent from the beginning.

The microscopic picture varies considerably, and in the atypical cases, which are numerous, the diagnosis is not easily made. The structure consists of varying amounts of lymphocytes, endothelial cells, eosinophils and endothelial giant cells. The presence of eosinophils is of importance in establishing the diagnosis. The reticulum is fine at first but gradually thickens (fig. 2).

*Clinical Course.*—No definite clinical course can be outlined since the progress of the disease in different persons does not present any uniformity. This fact alone makes the diagnosis uncertain unless biopsy is done.

There may be itching or eczema of the skin, with progressive weakness, but as a rule the first symptom is the enlargement of a chain of cervical, inguinal or axillary lymph nodes or dyspnea from bronchial occlusion by mediastinal nodes. Other nodes are involved later, and frequently the spleen enlarges. The blood shows a moderate secondary anemia, and the white count is usually normal except for a slight eosinophilia or slight lymphocytosis. As the disease progresses the anemia becomes pronounced; pressure symptoms on the trachea, esophagus or large vessels appear, and the patient becomes more and more cachectic. Death results from cachexia, terminal pneumonia or

TABLE 4.—*Hodgkin's Disease*

from pressure on vital structures. A rise in temperature, which is frequently intermittent, is common.

A study of table 4 shows that of the eight cases studied, five occurred in males and three in females. The youngest patient was 9 years old and the oldest 70. Contrary to the usual observation the disease appears most frequently in adult life, for with the exception of the 9 year old patient the average age was 50.

The cervical nodes are usually the first involved, but occasionally involvement of the axillary or inguinal nodes is first noticed. Mediastinal involvement usually occurs during the course of the disease, and in three cases of this series was noted early (fig. 3). In four cases there was a definite eosinophilia, an observation which is constant enough to be of diagnostic importance.

An enlarged spleen appeared in only one case, a condition which may help differentiate Hodgkin's disease from the leukemias, since in the latter splenomegaly is noted in about half the cases.

Numerous clinical types occur which have been grouped by Ewing as follows: (1) acute cases, (2) chronic generalized, (3) splenic Hodgkin's disease, (4) gastro-intestinal, (5) mediastinal, (6) abdominal, (7) Mikulicz's disease, (8) bone marrow lesions and (9) dermal lesions. This clinical classification is self-explanatory, being based on early or extensive involvement of particular organs or regions of the body.

*Prognosis and Therapy.*—Seven of the eight patients studied are dead, the average life after onset being nineteen months. One patient died four months after the onset, and one lived thirty-seven months. One patient is still living after forty months.

Fig. 3.—Hodgkin's disease, showing marked enlargement of the mediastinal nodes without evidence of the disease in the lungs.

In all, roentgen therapy was given to the involved nodes. Whether life was prolonged by this treatment is impossible to say, but in every instance there was a temporary regression in the size of the nodes and corresponding improvement in the general condition of the patient. It is believed, however, that the prognosis depends largely on the type of the process, for in the acute cases the duration of life is only a few months in spite of regression of the nodes following treatment. In spite of this pessimistic view, one cannot help believing that this treatment was of value in the following case:

CASE 2594.—A girl, aged 9, entered the Steiner Clinic on Oct. 10, 1927. For two years her mother had noticed an enlargement in the left side of the neck which recently had greatly increased in size (fig. 4 A). On examination, a chain of greatly enlarged nodes was found in the left side of the neck, extending from the ear to the clavicle. There were a few slightly enlarged nodes in the right side

of the neck, but no others were abnormal. The spleen was not palpable, and the x-ray picture of the chest was normal. Biopsy showed the typical picture of Hodgkin's disease.

From October, 1927, to August, 1928, both sides of the neck were irradiated. There was a slow but steady decrease in the size of the tumors until the nodes were reduced to practically normal size (fig. 4*B*). During this time, she gained rapidly in weight and strength.

In September, 1928, a large node was discovered in each axilla, and these areas have since been treated with favorable response.

#### LYMPHIOSARCOMA

Lymphosarcoma is a true malignant neoplasm which arises in lymphatic tissue, in either the nodes or other adenoid tissue. It is

Fig. 4 (case 2594).—*A*, Hodgkin's disease, showing marked enlargement of the cervical lymph nodes. *B*, same patient one year after treatment.

usually limited to this tissue, and extensions occur by way of the lymphatics, but true metastases to distant organs may occur. Starting in one chain, it spreads to others, or may be so rapid in its course that death occurs while the disease remains local.

The acute cases are characterized by their rapid invasive character which gives rise to necrosis and ulceration and result in early death. More often the process is widespread and more chronic. In this type frequently the only complaint was the presence of enlarged nodes, which persisted for several years before the fatal issue.

*Pathology.*—Gross examination of the affected node or chain shows the outline of the individual nodes, but there is a fusion caused by capsular invasion, rarely due to inflammatory reaction. The nodes are

soft and seem to bulge when bisected. Firm or hard nodes are not to be expected, as definite fibrosis is lacking except in long standing cases. Histologically, there is an obliteration of the usual architecture by a diffuse growth of lymphoid cells, either of small round cells (lymphocytes) or of larger round cells, derived from the reticulum cells. Giant cells are absent, but frequently there may be numerous multinucleated cells. Mitoses are frequent. The metastases show the identical structure, although a secondary inflammatory reaction may be marked (fig. 5).

*Clinical Course.*—Clinical types are grouped according to the point of origin as (1) cervical, (2) mediastinal, (3) gastro-intestinal and (4) pharyngeal.

Fig. 5.—Lymphosarcoma, showing diffuse cellular structure composed chiefly of large round cells (reticulum cell type).

Table 5 shows that fifteen patients of the forty-one studied were classed as having lymphosarcoma. Thirteen of these were males. It is essentially a disease of youth, the average age being 33. Eight patients were under 30, and of these, four were under 14.

In eleven the cervical region was first involved, but in most there was a spread to other regions. The spleen was enlarged in four instances, and metastases to distant organs were observed only twice.

As in Hodgkin's disease and leukemia, fever was frequently present. A leukocytosis ranging between 12,000 and 20,000 was constant enough to be of some diagnostic value. This leukocytic increase was largely

in polymorphonuclear neutrophils, and in only one instance was an abnormal number of eosinophils found. In most instances there was a moderate anemia, but many patients were robust and cachexia appeared late in the disease.

The clinical types are well illustrated by the following cases:

*Acute Generalized Type Without Metastasis.*

CASE 2651.—A boy, aged 5 years, had his tonsils removed on Aug. 11, 1927. Two weeks later, an enlarged node was noticed in the left side of the neck. Within a month after the tonsillectomy, there was a marked enlargement of the nodes in the neck, axillae and inguinal and epitrochlear regions (fig. 6). The tumors in the neck were so large that breathing and swallowing were difficult. By Oct. 1, 1927, there was ulceration over the swelling in the neck, and the tumors were red and tender. The temperature ranged from 100 to 104 F., and the pulse was rapid and irregular. The white blood cells numbered 19,000, of which 84

2681	M	22	Enlarged nodes	—	Cervical	4,500,000	15,000	—	Good	70 mo.+

per cent were polymorphonuclear neutrophils. Roentgen therapy to the neck did not cause regression in the size of the nodes, and the patient died, Nov. 3, 1927, from tracheal occlusion. At necropsy the mediastinal nodes were greatly enlarged and matted together. The retroperitoneal nodes were likewise the seat of the disease, but there were no metastases found in the lungs, kidneys, liver or any distant organ. The lymphatic tissue of the gastro-intestinal tract was not affected.

*Intestinal Lymphosarcoma with Metastases.*

CASE 1855.—A boy, aged 6 years, was well and healthy until December, 1924, when he developed intussusception of the ileum, which was reduced at operation. This appeared entirely successful until December, 1926, when he again developed intestinal obstruction. Operation was again performed and a segment of the lower ileum, which was obstructed by a growth, was resected. This growth was limited to the lumen of the intestine and metastases were not noted at operation. Microscopic section showed lymphosarcoma. The patient recovered from the operation but did not regain his weight and strength. Within a month the abdomen became distended with fluid, and a firm, nodular mass filled the right lower portion. Roentgen treatments to the abdomen caused no diminution in the size of the tumor. The fluid in the abdomen increased, and death occurred in February, 1927.

Fig. 6 (case 2651).—Acute lymphosarcoma. This patient did not respond to treatment and died two months after the onset of the disease.

Fig. 7 (case 2881).—Localized lymphosarcoma. Under roentgen therapy, the nodes entirely disappeared. The patient was alive and well five years after the onset of the disease.

At necropsy the abdominal mass was found to be made up of enlarged mesenteric nodes and of a tumor of the lower ileum. Small nodules of lymphosarcoma were found in the liver, spleen and the mediastinal and superficial lymph nodes.

*Localized Chronic Lymphosarcoma.*

CASE 2881.—A man, aged 22, first examined in January, 1928, was in robust health except for the presence of a chain of firm hard nodes in the right side of his neck. These nodes were first noticed five years previously and were removed by operation. A recurrence developed after operation, and the nodes gradually enlarged to their present size (fig. 7). A section from one of these showed it to be reticulum cell lymphosarcoma.

Three roentgen treatments were given the right side of the neck, with complete and rapid regression in the size of the nodes. In December, 1928, eleven months after treatment, a small recurrence was noted, and treatment is again being instituted.

Fig. 8.—Endothelioma of lymph node, showing diffuse infiltration and obliteration of lymphoid structures by large endothelial cells.

*Prognosis and Therapy.*—From the three cases just cited, it is seen that the duration of the disease is extremely variable. The patients, except in the acute or terminal stages, do not appear sick, and life may be prolonged for many years. Of the fifteen patients studied, seven are living, two six years after the onset of symptoms. This feature is in sharp contrast with the cases of leukemia and Hodgkin's disease in which the duration of life is much shorter and in which the patients appear sick from the onset of the illness.

Response to roentgen therapy is usually rapid both in regression in the size of the nodes and in the improvement of the health. So notable

is this that the response is of diagnostic value, since in other malignant diseases of the lymph nodes the improvement is slower and less marked. However, irradiation is only palliative, and the growths invariably recur. Recurrences respond less favorably to irradiation and finally reach a stage of radioresistance.

#### ENDOTHELIOMA

Primary endothelioma occurred in only three cases of this series. Two of these involved many nodes, metastasized to the lungs and were rapidly fatal. In the other patient, the disease has remained localized in the neck for five years and has responded rapidly and favorably to treatment. These cases represent the two clinical types of the disease; namely, the systemic and the localized. In both the outcome is eventually fatal, but in the latter the patient may remain in good health for several years.

*Pathology.*—This type of tumor was first described as a "primary carcinoma of the lymph nodes." There is frequently great difficulty in differentiating endothelioma from a metastatic tumor of epithelial

TABLE 6.—*Endothelioma of Lymph Nodes*

Case No.	Sex	Age	Complaint	First Nodes Involved	Red Blood Cells	White Blood Cells	Lung Metastases	Response to Therapy	Duration After Onset
1278	M	61	Enlarged nodes	Cervical	4,000,000	5,600	+	Temporary	20 mo.
693	F	50	Enlarged nodes	Cervical	4,700,000	6,700	+	None	12 mo.
1732	M	17	Enlarged nodes	Cervical	4,700,000	10,000	—	Good	5 yr.+

origin, and unless a definite primary tumor at some other point can be absolutely ruled out, a diagnosis of endothelioma can be made only with a certain amount of reserve. There is a uniform enlargement of the node, which is rather firm but not hard until late in the disease. Capsular invasion is not usual but is to be expected in recurring tumors. Cross-section shows an opaque surface with scattered areas of necrosis. Histologically, the typical picture is that of large, diffuse sheets of fairly large round cells, which appear first in the sinuses. The cells show a large vesicular and hyperchromatic nucleus with small, usually multiple, nucleoli. In differentiating between primary endothelioma and metastatic epithelial tumor, one must study the individual characters of the cells, the epithelial cell showing a slightly granular cytoplasm, a well marked nucleus, and a definitely rather large acidophil nucleolus. The lymphatic structure of the node gradually disappears as the growth of endothelial cells progresses, and fibrosis and necrosis occur later (fig. 8).

*Clinical Course.*—Clinically there is little to differentiate endothelioma from other malignant diseases of the lymph nodes. It may occur at any period of life, and the systemic form is usually regarded as Hodgkin's disease on account of the rapidity of the growth, the loss

of weight and strength and the widespread involvement. The blood count is usually normal, and there is no eosinophilia. Metastases to the lungs may be confused with secondary carcinoma (fig. 9). The localized form is usually found in robust young males, and the chronicity of the condition simulates certain types of lymphosarcoma. These two diseases respond so similarly to therapy that the diagnosis is established only by microscopic section.

The following cases illustrate the two varieties:

*Systemic Endothelioma of Lymph Nodes.*

CASE 1278.—A man, aged 61, noticed a small swelling in his neck in June, 1925. This grew steadily for one year, at which time he entered the Steiner Clinic. There was a hard, firm mass 4 cm. in diameter in the right supraclavicular region. He had lost steadily in weight and strength and had recently begun to cough. His

Fig. 9.—Endothelioma of lymph nodes, showing metastasis to the lung.

temperature, pulse and blood count were normal. Biopsy of the involved node showed it to be an endothelioma. A roentgenogram of the chest showed widespread metastases in both lungs. Roentgen therapy to the neck caused some diminution in the size of the node, but the general condition grew rapidly worse, and the patient died from terminal pneumonia in February, 1927.

*Localized Endothelioma of Lymph Node.*

CASE 1732.—A boy, aged 17, was first examined on Dec. 1, 1926. Three years previously he noticed a small nodule in the left side of his neck which gradually increased in size. During this time adjacent nodes enlarged, and at the time of examination the whole left side of the neck was filled with a firm, fixed group of nodes which were bound together (fig. 10 A). He had not lost weight, was working as a farmer, and was apparently in good health. The temperature and blood count were normal. A roentgenogram of the chest was normal. Biopsy of one of the cervical glands showed it to be endothelioma. The left side of the neck was irradiated from four directions, and within three weeks the nodes were reduced to practically normal size (fig. 10 B). To the present time there has been no recurrence.

## COMMENT AND CONCLUSIONS

This study of forty-one cases of malignant disease of the lymph nodes was undertaken in order to determine certain criteria by which differential diagnosis could be arrived at and at the same time to determine the effect of irradiation on this class of tumors. Although the number of patients is small, all have been personally observed, and the collective method of study has established certain basic facts on which conclusions can be based.

In the first place, irradiation seems by far the best method of treating these conditions which in the past have been subjected to operation. While not curative, it offers to the majority of patients definite pallia-

Fig. 10 (case 1732) —*A*, localized endothelioma of the lymph node. The nodes shown in this picture attained this size in three years. *B*, same patient three weeks later after roentgen treatment. Two years have elapsed without recurrence.

tion not only in the retardation of the growths but by an improvement of their general health. Especially is this true in lymphosarcoma and in certain forms of endothelioma. The duration of life is probably only slightly prolonged in Hodgkin's disease and in leukemia, but an improvement in subjective symptoms was usually noted. Only in acute leukemia does irradiation appear actually harmful.

Accurate diagnosis is an essential to treatment and prognosis, and with the exception of the leukemia, this can be attained only by microscopic section. Careful removal of tissue for examination has not appeared perceptibly to spread the process or to affect the clinical course.

Failure of the proper classification has led to much of the confusion which now exists concerning this group of malignant diseases, and it is possible that if a large number of cases are accurately classified and studied, sufficient clinical data may be obtained to make a diagnosis without the necessity of biopsy. For this reason, only those cases in which the diagnosis was unquestioned were here considered.

From the clinical course alone, certain facts concerning the diagnosis of these tumors have been gained. For example, prodromal signs of weakness, loss of weight and anemia often appear in leukemia before the enlargement of the lymph nodes, and a study of the blood will usually establish the diagnosis. On the other hand, in Hodgkin's disease and in lymphosarcoma the first sign is the presence of tumors of the nodes. In the former the patient appears sick; there is usually an eosinophilia; the response to irradiation is slow, and recurrence is rapid. In lymphosarcoma the patient is robust and healthy; leukocytosis without eosinophilia is present; the response to irradiation is rapid, and recurrence is late.

# TUMORS OF THE BRAIN AND SYPHILIS

PAUL MARTIN

There is a tendency in medicine for one to rely more and more on laboratory data and mechanical means of diagnosis. Tests which sometimes have only the appearance of exactness are always welcomed, and one overlooks the fact that they carry with them added causes of error, since their interpretation is often difficult.

I am far from denying that these tests are of value; many of them are excellent and have offered results which the mere clinical examination could not have given. The tests must be applied with an accurate technic and discussed with the greatest objectivity, and in establishing the diagnosis, the results of the clinical examination must always be given final consideration. Thus it is not the tests themselves that call forth criticism, but the interpretations put on their results which sometimes lead clinicians astray, thereby discrediting an accurate, valuable piece of information.

The Wassermann reaction is among laboratory tests the one which is the most largely used in the world's clinics. It has permitted the syphilitic origin of diseases hitherto classified without any understanding of their etiology to be recognized, and it has allowed great therapeutic success.

In the case of tumors of the brain, however, the misuse of the Wassermann reaction has spread wrong ideas and brought on confusion.

The opinion that the Wassermann reaction may be positive in non-syphilitic cases when the protein contents of the spinal fluid are increased, as for instance in the Froin syndrome and in cases of tumors of the brain and spinal cord, has been often expressed. This, of course, was calculated to destroy confidence in the Wassermann reaction and to deprive the neurologists of a precious means of differential diagnosis.

It has been recognized since that in spinal fluid, nonspecific fixation of the complement may occur when the fluid has not been heated to 56 C. (Noguchi,<sup>1</sup> Desneux<sup>2</sup>), and that an antigen composed of lipoids insoluble in acetone never gives a nonspecific fixation of the complement (Noguchi).

In a recent paper, Desneux suggested that if the American authors do not mention positive Wassermann reactions in cases other than syphilitic ones, it may be due to the fact that Noguchi's antigen is in general use in the United States.

1. Noguchi, H.: *Serum Diagnosis of Syphilis*, Philadelphia, J. P. Lippincott Company, 1911.

2. Desneux, J.: *J. neurol. et psychiat.* **27**:67 (Jan.) 1927.

Just recently, Spurling and Maddock,<sup>3</sup> who have studied a great number of spinal and ventricular fluids secured from Cushing's patients, concluded that the Wassermann reaction is always negative in cases of tumors of the spinal cord and brain.

The following brief history of a case<sup>1</sup> recently observed will illustrate this point of view.

#### ILLUSTRATIVE CASES

*History.*—Mrs. D. T., aged 35, complained of jacksonian fits and hemiplegia of the right side. The onset occurred six years before with difficulty in moving the right foot. This difficulty seemed to have been caused at first by a stiffness and afterward by a flaccid paresis. This extended by degrees to the leg and the knee, and walking became progressively unsteady.

Two years later, a neurologist was consulted and made the diagnosis of multiple sclerosis. A few weeks later, the patient had two jacksonian fits localized in the right leg. At that time, she was given antisyphilitic treatment.

A year before, the right hand and right arm were involved progressively. Four months before, there was a right jacksonian fit with participation of the right side of the face. After that time there was diffuse headache with prevalence in the left parietal and suboccipital regions.

*Neurologic Examination.*—Examination revealed the following: (1) spasmodic hemiplegia on the right side, with paresis of the right side of the face, deviation of the tongue and clonic seizures of the right leg; (2) very conspicuous dysmetria of the right hand in the finger-nose test with preterminal intentional tremor, and (3) no sensory disturbances, although there was a sensitive aura in the right half of the body. It was concluded that the lesion was of the left rolandic region (center of the foot) with irritation of the adjacent parietal area.

Lumbar puncture showed an initial pressure of 47 and a terminal one of 40 (Claude manometer), 11 cc. of clear fluid being removed. The analysis showed albumin 0.55 per cent with no cells. The Wassermann, Pandy and Benjoin reactions were negative.

Ophthalmoscopic examination showed that the fundus and perimetric fields were normal. The retinal pressure was: right eye, 35; left eye, 38, the arterial pressure being 12/9 (Pachon). Roentgen examination showed a decalcified area of the inner table in the upper left parietal region.

The diagnosis was tumor of the sensitivomotor region, presumably of meningeal origin.

The day before the operation, a note was received from a distinguished neurologist, which presented further information about the case and raised delicate controversy. This colleague was the one who had conducted the antisyphilitic treatment already referred to, and he wrote:

"I wish to give you a few retrospective details in order to complete your records and make your history of the case fit to serve eventually for the neurologist's benefit.

"A little more than two years ago, when I first saw the patient (I had already been in touch with the surgeon and asked him to operate on her) she presented

3. Spurling, R. G., and Maddock, C. L.: Cerebrospinal Fluid in Tumor of Brain, *Arch. Neurol. & Psychiat.* 14:54 (July) 1925.

4. I am indebted for this case to Dr. Ludo Van Bogaert, who took the clinical record and referred the patient to me for operation.

a right hemiparesis not involving the face and very marked at the upper limb; jacksonian seizures starting at the lower limb; Wassermann reaction negative in the blood, and no choked disks. Spinal fluid examination showed: pressure 23 (Claude manometer), patient lying down, a normal percentage of albumin, 3 cells, Wassermann ++++, colloidal Benjoin positive (September, 1924).

"I discarded temporarily the diagnosis of tumor and started an antiluetic treatment (arsphenamine, bismuth).

"This treatment brought on a progressive and very conspicuous regression of the symptoms. I made no further examination of the spinal fluid, the patient refusing lumbar puncture. Nevertheless at each series of treatment a further improvement was stated, so much that two years after starting the treatment, the patient was well except for a slight spasticity of the leg and that the arm had recuperated functions which it is not exaggerated to qualify as normal. The jacksonian fits were decidedly fewer and when they occurred they were very short (the patient was taking luminal). Several examinations of the eye revealed no lesions of the fundi.

"A year ago I started a course of treparsol and biquinyl treatments, which in my intention should have been the last. For the first time, the patient showed a bismuthic intoxication and a fortnight after the treatment was completed, series of violent fits with paralysis of the arm began. I proposed another lumbar puncture and had no more news from the patient.

"I was informed today of the decision you have come to after careful examination of the patient. At the present time, I agree that one should perform an exploration, but I should be surprised if you discovered a true tumor. It is possible after all, but it would be queer after such an astonishing improvement obtained following antisypilitic treatment, improvement which has persisted and increased during two years.

"There is only one operative observation which would explain the case to me, that is a localized cystic serous meningitis which could be the remains of a meningeal inflammation of syphilitic nature."

These remarks were impressive and calculated to shake a resolution even though it were well grounded.

*Operation and Course.*—My co-workers and I maintained our point of view, however, and the operation was performed on Dec. 13, 1927. With the patient under local anesthesia, a large left osteoplastic flap was turned down. There was no apparent hypertension. After the dura was opened, a reddish area was discovered at the upper rolandic region. The edge of the bony opening was rongueured to give more room.

The tumor was dissected away cautiously, and it appeared that its dural attachment was extremely narrow. This was resected together with the tumor (fig. 1). The dura was closed and the bone flap replaced.

On the second postoperative day, the patient had a jacksonian fit of short duration. On the fifth day, motion began to reappear on the paralyzed side. The patient improved steadily, and fifteen days after operation she could walk and feed herself.

The pathologic examination showed a round, hard, lobulated tumor with a diameter of approximately 6 cm. and weighing 125 Gm. The structure was that of a typical meningioma (fig. 2).

*Comment.*—The neurologist who first saw the patient thought at first that he was dealing with a tumor. The positive Wassermann

reaction of the spinal fluid made him change his mind, and he started antisyphilitic treatment. This test was made with nonheated spinal fluid, and that is the reason the reaction was positive.

In another group of cases one may find conspicuous cases of syphilis with a positive reaction of the blood and symptoms of involvement of the central nervous system.

Many physicians have their attention focused on the positive Wassermann reaction and apply antisyphilitic treatment; they overlook clinical symptoms which do not depend on syphilis and which demand treatment other than a specific one.

Fig. 1 (case 1).—Hard, round, lobulated tumor measuring 5 by 5 by 5 cm. The clearer patch in the center is the fragment of dura mater to which the tumor was attached.

*History.*—E. W., a carter, aged 29 years, was first seen in April, 1927, complaining of blindness, headaches and convulsive seizures localized on the left side. The malady began in June, 1924, when the patient complained of suboccipital headaches and failing vision. He consulted an internist, who found a four plus Wassermann reaction of the blood and sent him for treatment to a dermatosyphilologic clinic.

From 1924 to 1926, the patient was submitted to an intensive treatment. He received no less than five series of neoarsphenamine, three of bismuth and one of cyanide of mercury. Meanwhile the Wassermann reaction of the blood was still four plus, and the symptoms remained unaltered.

In 1925, the patient gave up all treatment. His headaches persisted, and his sight continued to fail. On April 4, 1927, he came to see us. At that time he was blind. Results of a general examination were negative, except for an old coxalgia on the left side.

*Neurologic Observations.*—The cranial nerves were normal except for blindness and secondary optic atrophy. Muscle power was diminished in the left upper limb;

Fig. 2.—Photomicrograph of the tumor shown in figure 1. The structure was that of a meningioma.

on the lower limb the results of examination were unreliable on account of the coxalgia. There were no superficial sensory disturbances. The deep sensibilities, however, were deeply altered on the left, where there was an astereognosis. On the left side the skin reflexes (cremasterian abdominal) were absent; a Babinski sign and an ankle clonus were present on the same side. There were no cerebellar symptoms.

The diagnosis was cerebral tumor of the right parietal lobe.

*Operations and Course.*—The first operation was performed on April 10, 1927. With the patient under local anesthesia, a large bone flap was turned down on the right side. The dura was tense and could be opened only after a lumbar puncture.

When the parietal lobe was punctured, a hard tumor was felt at a depth of 1 cm. and was encountered again in the temporal lobe at a depth of 4 cm.

The cortex was incised in the parietal lobe, and the tumor was found encapsulated and as large as the fist of an adult.

Since the blood pressure was greatly lowered, the operator felt that it was better to remove the tumor at a second stage, and the wound was closed in layers, the bone flap being removed. The patient made an uneventful recovery and was so greatly improved that he did not want to submit himself to the second stage of the operation.

Fig. 3 (case 2).—The smaller tumor is the fragment removed with the cautery in order to reduce the size of the tumor. The silk ligatures passed into the tumor were used as tractors. The whole tumor weighed 700 Gm.

On April 7, 1928, he returned to the hospital. At the operative site there was a huge hernia formed largely of spinal fluid, and the patient wanted to be relieved of this troublesome infirmity.

A second operation was performed on April 12, 1928. An incision was made around the former flap. The periosteum was stripped away, and a large arachnoidal cyst was opened. The tumor was partly exteriorized; it was enormous, vascular and adherent in the depth.

In order to reduce its size and facilitate its extirpation, a large fragment 5 by 5 by 5 cm. was excised with the cautery. In the cavity created in this way, heavy silk sutures were passed and tied. This permitted a traction on the tumor, and it was removed without difficulty (fig. 3).

It was attached at the lower border of the falx, and at its points of attachment a severe hemorrhage occurred. This was controlled by wet cotton and gauze, which were left in the wound. The galea and skin were sutured.

On April 14, 1928, forty-eight hours after the operation, the wound was reopened, the plugging was removed, the cavity was filled with saline, and the galea and skin were carefully sutured.

Fig. 4.—Low power magnification of photomicrograph of the tumor shown in figure 3. The structure was that of a fibrous meningioma.

Two days later, spinal fluid started to leak into the dressings. The fluid was cloudy and contained 150 cells per cubic millimeter; no bacteria were disclosed on direct examination. However, by cultures *B. antracomorphi*, *Diplococcus crassus*, a few staphylococci and rare streptococci were isolated. (The patient had impetigo of the scalp before the operation.)

During the following weeks, the brain expanded and took its original place, the leakage stopped, but the patient became gradually cachectic.

The patient's psychism remained intact until two days before death, which occurred seven weeks after the operation.

Pathologic examination showed an enormous, hard and lobulated tumor, weighing 700 Gm. At microscopic examination it appeared to be a typical meningioma (figs. 4 and 5).

*Necropsy.*—The brain was removed "en bloc," together with the skin overlying the bony defect, in order to allow an examination of the site of the operation. At

Fig. 5 (case 2).—High power magnification of photomicrograph of the tumor shown in figure 3.

the base, there were a few patches of meningitis. A transverse section passing through the middle part of the flap showed that the brain had regained its place. At the level of the falx, there was a small collection of pus. On the left side of the falx, there was a tumor nodule as large as a hen's egg which was left at the operation.

The patient died of meningo-encephalitis

## COMMENT

1. The physician who first saw the patient ascribed the symptoms (headaches) to syphilis of the central nervous system due to the presence of a four plus Wassermann reaction.

2. The antisyphilitic treatment was given in a specialized clinic and continued in spite of the fact that it did not bring about any improvement.

3. As far as the surgical management of the case is concerned, it might have been better to have tried to control the bleeding before closing and not by using a buried plugging. This might have prevented the cerebrospinal leakage and infection.

When a patient presents a positive Wassermann reaction, it is not a sufficient reason for ascribing all the symptoms he complains of to syphilis.

One should never continue an antisyphilitic treatment which does not cause improvement, and one should look further to establish the correct diagnosis. These two errors were made by highly trained and conscientious physicians; that is the reason I think it worth while to attract attention to such a case.

These two cases illustrate the commonest mistakes into which physicians are induced when the differential diagnosis between tumor of the brain and syphilis of the central nervous system must be made. In both cases the mistakes were due to misuse of the Wassermann reaction which, in so many instances, has been of great value. In the first case, a faulty technic was responsible for the error; in the second case, the mistake came from a misinterpretation of the reaction.

The Wassermann reaction of the spinal fluid should be made with a strict technic on fluid heated to 56 C. A positive Wassermann reaction of the spinal fluid does not necessarily mean that one has to deal with cerebrospinal syphilis. Dujardin has shown that syphilitic antibodies formed in the blood pass through the meninges because of a permeability which may be caused by pathologic changes other than those of syphilis.

In cases in which there is an indubitable underlying syphilis, a "traitement d'épreuve" may be instituted, but the case should be watched carefully, and when the nervous symptoms do not yield to the treatment, the patient should be reexamined.

The prevailing idea about a systematic "traitement d'épreuve" in cases of tumor of the brain is due to the fear of surgical intervention which is by no means without risks, but which is the only therapeutic measure which can be looked on when a patient is harboring an intracranial neoplasm.

Not only is surgical intervention the sole form of therapeutics to be applied to tumors of the brain, but even in cases in which the presence

of syphilis of the central nervous system is positive, it may have imperious indications. This is illustrated by the record of another patient.

*History.*—B. E.,<sup>2</sup> a laborer, aged 25 years, was treated for secondary syphilis in April, 1926. He was given three series of neoarsphenamine at intervals of one month, with total doses respectively, of 5.10, 6.25 and 4.95 Gm., the maximal dose at a single injection being 0.9 Gm.

During the intervals of each series, the patient experienced severe headaches, which at first improved when the treatment was resumed but which later were not influenced by the injection of arsphenamine.

On Dec. 9, 1926, a lumbar puncture was done. The spinal fluid showed: 355 cells per cubic millimeter and a positive Wassermann reaction; the Wassermann reaction of the blood was negative.

After this examination a mixed treatment (neoarsphenamine, sulpharsphenamine at the maximal dose of 0.6 Gm. potassium iodide, bismuth and mercury) was started. The treatment had hardly any influence on the headaches, which at times became unbearable. The general condition of the patient became poor, and he was discouraged.

In May, 1927, while being submitted to intravenous injections of cyanide of mercury, the patient suffered from severe headaches accompanied by attacks of vomiting. His general condition became poorer and poorer, and on the night of June 2, 1927, he was taken to the hospital in an unconscious condition.

His pulse rate was from 45 to 50, weak and irregular. I immediately performed a subtemporal decompression on the right side. On the following day the patient felt better, and the headaches had subsided.

The antisyphilitic treatment was continued and well borne. The patient was cured of his symptoms.

*Comment.*—1. It seems that symptoms of intracranial hypertension may appear during the course of a recent syphilis and be at once unyielding to a mixed and intensive antisyphilitic treatment.

In this case, the diagnosis was easily made on the grounds of the patient's history and the result of the lumbar puncture.

In cases in which the syphilitic origin is ignored (the blood indeed may present a negative Wassermann reaction), an examination of the spinal fluid will be indicated.

2. It is remarkable that before the decompressive operation the antisyphilitic treatment was without effect and that after decompression it acted energetically. When looking for an explanation, one should think that intracranial hypertension, in lessening the circulation of blood at the site of the lesion, interferes with the bathing of the diseased brain by the drug.

---

5. This patient was referred to me by Dr. B. Dujardin, and was presented to the Groupement belge d'Etudes oto-neuro-oculistiques et neuro-chirurgicales; Dujardin, B., and Martin, P.: *J. de neurol. et de psychiat.* 28:228, 1928.

It seems that in some cases a decompressive operation should be recommended not only as an emergency measure but also as having an added therapeutic action in cases of cerebral syphilis unyielding to antisyphilitic treatment.

#### CONCLUSIONS

1. In cases of tumors of the brain the interpretation of a positive Wassermann reaction should be submitted to severe criticism.

2. The test should be made on spinal fluid heated to 56 C. or on nonheated spinal fluid with nonprotein-trophic antigen (Noguchi, Bordet) in order to avoid nonspecific positive reactions.

3. The presence of an undoubted positive reaction even of the spinal fluid does not necessarily mean that the symptoms of involvement of the nervous system are due to syphilis, and if an antisyphilitic treatment is given, it should not be continued when the symptoms remain unaltered.

4. The routine antisyphilitic treatment given too often in cases of tumor of the brain should be abandoned; the only treatment should be surgical, sometimes with adjunction of deep roentgen therapy.

5. Even in undoubted cases of cerebral syphilis the symptoms may demand surgical relief, and the operation may in certain cases favor the medicinal action which was previously of no avail.

# THE EFFECT OF ULTRAVIOLET LIGHT ON CORNEAL TUBERCULOSIS IN RABBITS\*

HARLAN F. NEWTON

Experimental evidence which can shed light on the activity of the tubercle bacillus in tissue and its resistance to modern methods of therapy is of value. The advent of the use of heliotherapy has marked a great advance in the physiotherapy and control of many forms of local tuberculosis. A particularly significant addition to the medical armamentarium was the air-cooled quartz mercury vapor lamp, commonly spoken of as the ultraviolet lamp or the Alpine sun lamp.

In the world at large, sunlight is the great destroyer of bacteria, and even in the animal body, if the effects of its indirect action are considered, it must be given first place. Sunlight in many countries, however, is available for only short periods of the year, and even then is an uncertain therapeutic and experimental agent, due to weather conditions. This has limited its value and led to the creation of substitute sources of ultraviolet light. The spectral characteristics of the different types of artificial light are important and different. Reyn<sup>1</sup> has stated that the spectrum of the carbon arc light is a continuous one, which, consequently, contains all the rays and notably all the chemical rays that penetrate well into tissues; while the different types of quartz mercury vapor lamps have a linear spectrum, the lines of which are especially strong in the short-waved ultraviolet rays of comparatively feeble penetration. Many of the older writers, Hasselbalch,<sup>2</sup> Henri,<sup>3</sup> and Glitscher,<sup>4</sup> stated that the penetration of the shorter ultraviolet rays through the skin is for the most part not more than 0.1 mm. These investigators worked with dead epidermis which differs markedly from living protoplasm in its biologic aspects, and also in its physical and chemical properties. Macht,<sup>5</sup> on the other hand, studying the penetration of the

ultraviolet rays from the Alpine sun lamp by means of a spectrograph and thermopile, and using living animal tissue, found that the short ultraviolet rays (less than 3,025 angström units) pass through a thickness of skin of 1 mm. or more. He definitely established the fact that penetration of ultraviolet rays through the living skin and other tissue is greater than has hitherto been supposed, and also that some of the shorter ultraviolet rays penetrate skin more deeply than the longer ultraviolet rays.

Henri and Baroni<sup>6</sup> showed that virulent bovine tubercle bacilli, when suspended in a physiologic solution of sodium chloride and placed 15 cm. beneath the quartz mercury vapor lamp, lost their acid-fast property after three to four minutes of irradiation, and were destroyed in ten minutes. Eidinow<sup>7</sup> recently confirmed these observations, and also demonstrated that the short ultraviolet rays (those less than 3,300 angström units) of the lamp possess the greatest bactericidal effect on tubercle bacilli suspended in a physiologic solution of sodium chloride. Perhaps his most significant contribution, however, was finding that virulent tubercle bacilli mixed with blood or serum and exposed in a very thin film were not killed, by sixty minutes' irradiation, while staphylococci prepared similarly showed attenuated virulence in thirty minutes and destruction in sixty minutes. Since tubercle bacilli mixed with blood or serum are not destroyed in vitro, it might seem improbable that any irradiation with the quartz mercury vapor lamp of tubercle bacilli in vascular tissues can result in direct bactericidal action.

The effect of ultraviolet light on lupus vulgaris has naturally attracted the attention and observation of many authors. From 1902 to 1905, Jansen,<sup>8</sup> Klingmüller and Halberstädter<sup>9</sup> and Nagelschmidt<sup>10</sup> reported that the rays of the Finsen concentration lamp can completely destroy tubercle bacilli in a lupus lesion to a depth of 1.5 mm. in seventy-five minutes' irradiation; but as the lupus nodules are usually situated from 2 to 4 mm. below the surface of the skin, only a weak effect to this depth was observed. Further, they found that guinea-pigs into which had been injected ground extracts of irradiated lupus nodules died of tuberculosis. Virulent tubercle bacilli were also injected subcutaneously and intradermally into guinea-pigs, the site of inoculation

being immediately irradiated; but later all the animals were found to be suffering from generalized tuberculosis. Single irradiation in these early clinical cases of lupus may account in part for the negative results. The many reports of the cure of lupus vulgaris by repeated treatment with the ultraviolet lamp establish the value of heliotherapy. Theoretical reaction of the tissues or possible overheating of the part have been advanced to explain the results which have been obtained, but experimental proof is still lacking. While the chronic tuberculous diseases of the skin and mucous surfaces respond admirably to ultraviolet radiation, the tubercle bacillus is an organism which is more resistant to the rays of the ultraviolet lamp than the staphylococcus, and apparently is sensitive only to the shorter ultraviolet rays from which it may be protected by the tissues.

The eye has been particularly employed in investigations concerning the etiology of tuberculosis and the histogenesis of the tubercle (Schieck,<sup>11</sup> Jansen,<sup>12</sup> Baumgarten,<sup>13</sup> Heydemann<sup>14</sup> and Calmette<sup>15</sup>). Most of these authors produced tuberculosis of the iris or of the anterior chamber by injection, or infected the cornea alone by tattooing or by intralamellar injection. Jansen and his co-workers at the Finsen Institute, Copenhagen, have studied the histologic changes resulting from the use of ultraviolet light on tuberculosis of the iris and anterior chamber. One irradiation of one hour's duration was given with the Finsen concentration lamp from three to six weeks after the ocular tuberculosis was well advanced. He found no retardation of the progress of the disease resulting from this light treatment. The Finsen lamp differs markedly from the ordinary quartz mercury vapor lamp, but it seems improbable that one irradiation with either lamp could sterilize a well advanced ocular tuberculosis. These results are, therefore, not particularly significant. The literature contains no evidence of the effect of repeated irradiation of experimentally produced corneal tuberculosis with ultraviolet light, and these possible effects excited my interest. The cornea of the rabbit is particularly suitable for the elucidation of this study, for it is an essentially avascular tissue, not more than 1 mm. thick, and allows free passage of all the short ultraviolet bactericidal

rays. It can also be easily infected by intralamellar injection with no possibility of secondary infection or contamination, and daily observations can readily be made. My purpose, therefore, in this work was to observe (1) the effect of repeated direct ultraviolet irradiation with the air-cooled quartz mercury vapor lamp on the corneas of rabbits into which was injected a suspension of tubercle bacilli (*a*) before any gross infection was apparent and (*b*) after the infection was established and evident; and (2) the indirect effect on corneal tuberculosis of repeated irradiation of one half of the body surface of the rabbit.

#### METHOD

Twenty-two white, young rabbits, weighing between 1,800 and 2,600 Gm. each, were used in these experiments. They were kept on the usual herbiferous diet, isolated from other animals, groups of four or five occupying large roomy cages indoors, the latter never being exposed to direct sunlight. During the experimentation eight of the rabbits contracted an acute coryza, five of the smaller ones succumbing early in the work. All the other animals were healthy and active at all times.

After the method of Calmette,<sup>15</sup> known virulent bovine tubercle bacilli in pure culture grown on egg medium and suspended in glycerin-dextrose-distilled water solution were used for injection. This emulsion was diluted with a normal sterile physiologic solution of sodium chloride so that by count 0.03 cc. of the solution contained about 300 tubercle bacilli. Both corneas of all the animals were injected with this same amount of solution of bacilli on the day of its preparation. Before each inoculation the injecting syringe was filled from the constantly rotated tube containing the bacillary suspension in order to prevent sedimentation of the bacilli, and so that, so far as was possible, 300 tubercle bacilli would be injected into each cornea. Except for the five treated corneas of the second group, definite tuberculosis developed in both corneas of all the animals.

The animals were prepared for injections into the corneas in the same way as they were for ultraviolet light treatment. The rabbit was rolled in a small sack, only the head protruding, the legs thus being confined and restrained. Only the eyes were cocaineized. By means of an ocular elevator the eye was gently dislocated and held in light spring forceps. A fine needle fitted to the syringe containing the bacillary emulsion was then inserted into the outer portion of the cornea, and carried centrally in the intralamellar substance so that the injection was made in the exact center of the cornea. The point of puncture was first sterilized with a small amount of tincture of iodine, and on withdrawal of the needle, gentle pressure with a small swab impregnated with the same solution sealed the injection-channel and prevented escape of the emulsion. The anterior chamber was never entered.

The ordinary type of air-cooled quartz mercury vapor lamp was used for treatment. Because the intensity of light produced by these lamps varies, weekly tests on those used in this work were made. An intensiometer gave the exact number of minutes which produced dermal erythema with the object 40 cm. distant. This is important, for while four minutes' exposure was at one time enough to produce erythema, often nine minutes with that lamp was required for the same effect a week later. Therefore, for the sake of uniformity in the effect of light treatment on the animals, the number of erythema doses was always used as the unit, and the exact time of exposure disregarded. Previous workers always considered the intensity of light delivered by the quartz mercury vapor lamp the same at all times.

This is not true. Before treatment of the cornea the rabbit was confined and restrained in a small sack, the head protruding, the eye to be treated cocainized. The eye was then gently dislocated as for injection and held in spring forceps. By means of a "window" held 0.5 cm. above the cornea, all parts of the animal except the cornea were protected and screened from the rays of light. Exposure was at 40 cm. distance, usually for five erythema doses. In testing the tolerance of the cornea to the light, it was found that seven and ten erythema doses produced marked conjunctivitis and ocular actinic inflammation which required six days to subside. Five erythema doses, though far from being reactionless, could be given more often, seemed more satisfactory, and was therefore the unit selected. To prevent a burn of the cornea 1 or 2 drops of a physiologic solution of sodium chloride were dropped on it during the period of exposure.

### RESULTS

**GROUP 1: Control Animals Not Exposed to Ultraviolet Light.**—Two of the five animals in this group died of acute coryza two weeks after corneal inoculation. Of the fourteen surviving rabbits in the other groups that had been treated by light, only one eye of each animal was subjected to ultraviolet light. The other served as a control, and the development and progression of the tuberculosis in these corneas was not different from that in the three unexposed control rabbits. For between twenty-three and twenty-seven days after corneal inoculation the eyes appeared perfectly normal. A fine gray point or narrow streak in the cornea accompanied by slight conjunctivitis then appeared. This initial point gradually enlarged, the conjunctivitis and iritis became marked, only to disappear in a few days and other similar foci appeared in the corneal centrum and in the inoculation channel. These became confluent, and a small gray ulcer was formed between the forty-third and fifty-first day. Almost coincidentally with the appearance of the ulcer, a fine blood vessel pannus arising from the conjunctiva on all sides radiated into the cornea (fig. 1 a). About the fifty-seventh day the ulcer, 1 cm. in diameter, was completely vascularized. The development of complete ulceration of the cornea then progressed peripherally and more slowly (fig. 2 a). The animals were killed on the ninety-seventh day after inoculation. The cervical and bronchial lymph nodes, spleen, lungs and liver (in one rabbit) were filled with caseous and fine foci from which pure cultures of tubercle bacilli were recovered. Histologically, the corneas (fig. 3 a) showed marked thickening, complete erosion of the outer layer of epithelium with marked endothelial cell and lymphocytic invasion of the corneal substance. Dilated blood vessels surrounded by lymphocytes and, in places, caseous foci were seen. The picture was that of unquestionably advanced tuberculosis.

**GROUP 2: Effect of Ultraviolet Light on Corneas Given Injections of Tubercle Bacilli But Not Showing Evidence of Tuberculosis.**—There were five animals in this series, the sixth dying of acute coryza early in the work. One eye of each rabbit was untreated with light and there-

Fig. 1.—*a*. Control cornea of rabbit 661 (group 2), sixth week after inoculation, showing beginning ulceration and pannus-formation. *b*. Cornea treated with ultraviolet light. No evidence of tuberculosis. Slight subsiding actinic inflammation.

Fig. 2.—*a*. Control cornea of rabbit 661 (group 2), eighth week after inoculation, showing advanced tuberculous ulceration. *b*. Cornea treated with ultraviolet light; normal.

Fig. 3.—*a*. Control cornea of rabbit 661 (group 2), fourteenth week after inoculation. Thickening of cornea, erosion of the epithelium, dilatation of blood vessels, endothelial cell and lymphocytic infiltration, and foci of caseation are seen; advanced tuberculosis. *b*. Satellite cervical lymph node; caseous tuberculosis. Hematoxylin eosin stain; reduced from magnification  $\times 150$ .

fore they were added controls to group 1. The other eye was used for light treatment. Twenty-four hours after corneal inoculation, in order to allow any traumatic inflammation resultant from it to subside, the treatment was started. Four exposures of five erythema doses were then given to each animal at three day intervals. Thereafter no light treatment was given. Widmark,<sup>16</sup> Ogneff<sup>17</sup> and Verhoeff,<sup>18</sup> studying the influence of ultraviolet light from the carbon arc lamp on the normal eye of the rabbit, described pericorneal injection, chemosis, clouding of the cornea, sometimes superficial corneal ulceration, increased vascularity to the cornea and conjunctivitis. In control experiments with light not containing the ultraviolet spectrum, there were practically no changes. In this series the same effects were observed as by the aforementioned authors, except for superficial corneal ulceration. All clinicians recognize the conjunctivitis which follows careless exposure of the human eye to the rays of the Alpine sun lamp. There must be, therefore, unpreventable more or less severe actinic inflammation with exposure to the ultraviolet lamp, dependent on the intensity of the light. Six weeks after inoculation, when the control cornea showed beginning ulceration and vascularization with advancing development of the tuberculosis (fig. 1 *a*), the treated cornea had never shown any evidence of tuberculosis. Only slight vascularization of an essentially clear cornea from subsiding actinic inflammation was observed (fig. 1 *b*). At the end of the eighth week, the control corneas showed extensive tuberculous ulceration (fig. 2 *a*), while the treated corneas were wholly clear (fig. 2 *b*) and remained so in all five rabbits until the animals were killed for postmortem examination at the end of the fourteenth week. Gross study then revealed small and large caseous foci of tuberculosis in the control corneas, their satellite cervical lymph nodes, spleen, and bilaterally in the bronchial lymph nodes and lungs. Cultures of tubercle bacilli were recovered from lesions of these organs. Histologically, the control cornea (fig. 3 *a*) and a cervical lymph node from that side (fig. 3 *b*) showed typical microscopic tuberculosis. On the other hand, the corneas treated with light and their satellite cervical lymph node chains were grossly normal. Histologic preparations are confirmatory in showing a normal cornea (fig. 4 *a*) and a normal cervical lymph node (fig. 4 *b*).

It might be argued that as treatment of these corneas was begun before the appearance of a tuberculous lesion, there might have been some mistake in inoculation, and few if any tubercle bacilli might have

been injected. Using the same bacillary suspension and technic, all the animals were injected at the same time and in the same manner. That tuberculosis developed in the corneas of all the other animals makes it unlikely that faulty technic was the cause of negative results in the treated eyes of these five rabbits. There is but one reasonable explanation of these results. Four ultraviolet irradiations by means of the air-cooled quartz mercury vapor lamp destroyed virulent tubercle bacilli soon after their injection in the cornea of the eye of the rabbit and before macroscopic tuberculosis could develop.

**GROUP 3: *Effect of Ultraviolet Light on Macroscopically Evident Corneal Tuberculosis.***—One of the six rabbits in this group also died of acute coryza early in the work. As in the previous experiments (group 2), one eye of each of these five animals was unexposed to ultraviolet light, and therefore acted as an added control to group 1. Between the twenty-third and twenty-seventh day after corneal injection with tubercle bacilli, a gray lesion the size of a pinhead, associated with conjunctivitis and slight iritis, first appeared in the centers of the corneas of all the control animals. This was the primary evidence of the definite development of tuberculosis in the cornea after the period of incubation. At this time, therefore, treatment with ultraviolet light by the air-cooled quartz mercury vapor lamp was begun, one cornea of each of the five animals being used. Between nine and eleven separate exposures of five erythema doses at intervals of from three to four days were administered. All parts of each rabbit except the cornea were carefully screened from direct or indirect irradiation.

The treatment with light caused an acceleration of the ulceration and an earlier vascularization of the corneal lesions by comparison with the control corneas. No direct complete sterilization of the diseased corneas by repeated strong exposure to the ultraviolet light or indirect retardation of the tuberculosis through stimulation of an increased inflammatory cell reaction was observed. Cultures of virulent tubercle bacilli were obtained from these treated corneas as well as the generalized lesions found when all the animals were killed at the end of the fourteenth week after inoculation. The histology of the irradiated corneas was also not different from that of the control rabbits except for greater vascularity and more abundant infiltration of endothelial cells and lymphocytic cells throughout the corneal substance.

**GROUP 4: *Indirect Effect of Ultraviolet Irradiation of One Half of the Body Surface of the Rabbit on Corneal Tuberculosis.***—Only four of the six rabbits in this group survived the experiment. These animals were large, young white rabbits, into the corneas of which tubercle bacilli had been injected simultaneously and in the same manner as into the animals of the previous groups. The hair of one side and of the abdomen of these rabbits was cleanly removed by shaving, without irritation of the underlying skin. Later growth of hair in these

parts was removed in a similar manner from time to time. The skin of an albino rabbit is comparatively thin, lacking in pigmentation, and presumably should allow ready passage of the ultraviolet rays of light (Macht<sup>5</sup>). Twenty-four hours after corneal inoculation with tubercle bacilli, treatment of the exposed body surface of the rabbits with ultraviolet light from the air-cooled quartz mercury vapor lamp was begun. To prevent excessive irritation or possible burning of the skin from irradiation, only one half of an erythema dose was given at the first exposure. This amount was gradually increased daily. In three weeks, or just before the appearance of the corneal tuberculosis, the skin was slightly pigmented and tolerated five erythema doses of light exposure without reaction. Further treatment was given with this amount of light every second or, occasionally, third day for the next five weeks. Both corneas of each rabbit were screened from the direct ultraviolet light during treatment. They, therefore, acted as indexes of the indirect antibacterial action of ultraviolet radiation of one half of the body surface of the rabbit on corneal tuberculosis. No appreciable retardation of the development of the local corneal tuberculosis in either eye was observed, nor did postmortem examination at the end of the fourteenth week reveal evidence of the localization of the disease to the corneas, all the animals showing generalized tuberculosis proved bacteriologically.

#### SUMMARY

1. The cornea of rabbits because of its ready accessibility, uniform thickness and avascularity is particularly suitable for the study of the effect of ultraviolet light on the action of virulent bovine tubercle bacilli in tissue.
2. The production, development and progress of experimental corneal tuberculosis in rabbits is described.
3. Corneas injected with virulent tubercle bacilli, but showing no gross tuberculous lesions, were each exposed to ultraviolet irradiations from the air-cooled quartz mercury vapor lamp. The bacilli were destroyed, and the subsequent development of corneal tuberculosis prevented.
4. Observations were made on animals with early macroscopic corneal tuberculosis treated with repeated ultraviolet irradiation. There was no sterilization of the diseased corneas or retardation of the tuberculosis through stimulation of an increased inflammatory cell reaction. The ultraviolet light accelerated the ulceration of the lesions and increased the vascularity as well as the endothelial cell and lymphocytic infiltration of the corneas.
5. Ultraviolet radiation of one half of the body surface of the rabbit produced no observable indirect antibacterial effect on the germination of corneal tuberculosis.

# INTRACRANIAL COMPLICATIONS IN PURULENT OTITIS MEDIA

WILLIAM C. WARREN, JR.

The more cases one sees of discharging ears, the more one should learn to respect them. In making this statement no special type in particular is referred to but all types in general. There is no other condition in medicine that carries with it more potentiality of complications; consequently, every case of *otitis media* should be approached with fear and trepidation. What may happen next is an important question and usually is the cause for considerable thought and anxiety on the part of the attending physician.

In this ever progressing era of medicine much has been accomplished in the diagnosis and treatment of intracranial complications which are otogenous in origin, but much more still remains unsolved. The mortality rate continues to be high and at times seems discouraging. A review of the literature on this subject for the past fifteen years, however, reveals much success in the treatment of sinus thrombosis, some success in the treatment of abscess of the brain and little success in the treatment of meningitis. Progress in the treatment of the latter depends on a more thorough and general understanding of the anatomy and physiology of the pia-arachnoid. The fact that meningitis is the most common otologic intracranial complication makes it all the more important.

Most authorities agree that about one of every four cases of chronic infection and one of every nine cases of acute infection of the middle ear present an intracranial complication. The mortality is practically the same, though slightly higher in the acute cases. This may be explained by the frequent absence of typical signs and symptoms and the watchful waiting attitude assumed by many.

The following is a classification one should always keep in mind when dealing with a case of suspected intracranial lesion arising from an infected ear: (a) circumscribed, (b) diffuse and (c) combination of these two. Abscess of the brain would come under (a), meningitis under (b) and sinus thrombosis under (c). It is true that meningitis may be local or general, but the cases most frequently seen are those of a diffuse purulent leptomeningitis.

Shuster<sup>1</sup> of Philadelphia has well said:

There is not a group of cases in the domain of surgery wherein the patient's condition is more serious, and the evidence upon which operating must be undertaken more meager, nor the effects of mistaken surgery more disastrous.

---

1. Shuster, B. H.: Intracranial Complications of Otitic Origin with Reference to Diagnosis and Management, *Laryngoscope* 37:897, 1927.

In chronic purulent otitis media we have to be pushed before we dare diagnose or even awake to the suspicion of intracranial disease. This is particularly true in those cases of chronic purulent otitis media with very little or occasional recurrent moisture. The patient becomes sick suddenly and we think of everything but ear and intracranial complication.

The symptoms which, in combination or alone, should turn one's attention to the head are: (1) headache, (2) vomiting, (3) vertigo, (4) fever, (5) chills and (6) disturbed ratio between pulse, temperature and respiration.

Slowing of the pulse rate is observed in from 30 to 65 per cent of most cases of intracranial disease. It seems that this is probably due to toxic irritation of the vagus center. The mortality is much greater in cases with bradycardia than in those in which the pulse rate corresponds to the temperature.

I shall discuss at length only the three most common types of intracranial complications. Bowers<sup>2</sup> reported two cases of cavernous sinus thrombosis associated with (1) acute purulent otitis media and (2) mastoiditis. Maybaum<sup>3</sup> reported one. This is a rare condition, with about twenty-six cases reported in the literature. The onset is usually sudden, and the duration is short. The usual symptoms in all cases are: ophthalmoplegia, proptosis, chemosis, tortuosity of the veins of the fundus with possibly retinal edema and hemorrhage. Culture of the blood is nearly always negative. The commonest route taken by the infection is through the superior and inferior petrosal sinuses with the lateral sinus often not involved. The prognosis is always serious and usually fatal. This condition is often unsuspected and diagnosed only at autopsy.

Lampe<sup>4</sup> reported a case of fracture of the skull following a radical mastoidectomy simulating abscess of the brain. When the patient was admitted to the hospital one month after operation, he was in a semi-comatose state and complained of severe pain on the affected side of the head and projectile vomiting. The pulse rate varied from 60 to 65. The right pupil was dilated and reacted sluggishly to light and in accommodation. There was external strabismus; the spinal fluid was under great pressure but was otherwise normal. Operation revealed a fracture of the squama which in turn had caused an injury to the posterior branch of the middle meningeal forming a large blood clot. The

external strabismus and dilated right pupil cleared up while the patient was on the operating table after removal of the clot.

A case of multiple abscesses of the brain reported by Coates and Case,<sup>5</sup> with several others, seems to bear out the fact that these abscesses are embolic in origin and arise from an infection of the blood stream.

Extreme rheumatoid arthritis complicating a case of lateral sinus thrombosis was reported by Alden.<sup>6</sup> This is interesting because of the clearcut picture produced by this type of focus of infection.

A short review of the anatomic considerations is necessary for full appreciation of the discussion which is to follow. The petrous bone has four surfaces: (1) anterior, (2) posterior, (3) inferior and (4) lateral. The inferior surface is the least important, because it has little to do with intracranial complications; this is also true of the lateral surface. The only important landmark on the anterior surface is the eminentia arcuata behind which lies the superior semicircular canal. The convexity of the latter is in proximity to the floor of the middle fossa, and infection passing through this route produces an abscess of the temporal lobe. The posterior surface is the most important because so many intracranial complications go through this way. Complications of the inner ear pass through the posterior surface, and complications of the middle ear through the tegmen tympani or convexity of the superior semicircular canal. The important landmarks on the posterior surface are: (1) aqueductus vestibuli which is the communication between the endolymphatic space of the inner ear and the endodural space; (2) aqueductus cochleae which is the communication between the perilymphatic space of the inner ear and the subdural space of the brain; (3) fossa subarcuata which is rudimentary in human beings and contains only connective tissue, and (4) internal auditory meatus.

I may also add that, as a rule, suppurations which go from the inner ear into the brain through fistulas due to pathologic conditions produce abscesses, and those which pass from the inner ear into the brain through natural ways produce diffuse meningitis. The important exception to these rules is the infection that passes through the aqueductus vestibuli; it usually produces abscesses.

#### INTRACRANIAL COMPLICATIONS

*Lateral Sinus Thrombosis.*—The frequency of this condition is from 3 to 5 per cent.

*Etiology and Pathology:* Chronic mastoiditis and cholesteatomas produce the majority of cases of lateral sinus thrombosis. Diminished

5. Case, E. A., and Coates, G. M.: *Ann. Otol. Rhin. & Laryng.* **33**:335, 1924.

6. Alden, A. M.: *Lateral Sinus Thrombosis with Extreme Rheumatoid Arthritis*, *Ann. Otol. Rhin. & Laryng.* **35**:561, 1926.

resistance and virulent organisms are the chief factors. This statement is supported by the fact that this complication occurs more frequently in children with disease of the middle ear complicating an acute exanthem that has caused severe depletion, when the offending organism is usually *Streptococcus hemolyticus*.

The diagnosis would be easy in every case if all the typical symptoms were present, but unfortunately these are frequently absent. No cases in which surgical intervention is indicated calls for more experience or better judgment than do such cases.

The most outstanding symptoms in lateral sinus thrombosis seem to be the euphoria and the wide, sharp oscillations of temperature. These two symptoms are usually present. Bacteremia may or may not be present. A negative culture does not exclude sinus thrombosis, nor does a positive one clinch the diagnosis. In about one of every four cases is there a positive bacteremia. Although a number of cases of lateral thrombosis in which chills did not occur have been reported, one should be constantly on the lookout for this ever important symptom. Leukocytosis with a fairly high polymorphonuclear count is usually present, although not so high as in meningitis or abscess of the brain. If fever reappears after an interval of normal temperature which has followed the establishing of adequate drainage in a case of mastoiditis, one should always be suspicious of a sinus infection. A sudden reappearance of fever after an acute purulent otitis media has been cured for some time should also bring the foregoing diagnosis to mind.

Diagnosis: In the differential diagnosis, one must rule out typhoid fever and malaria.

Treatment: Otitides of more than two weeks' duration which present a picture of sepsis otherwise unaccounted for should be studied with the possibilities of a sinus thrombosis in view, and a blood culture should be taken. If the blood test is repeatedly negative, the clinical signs should determine whether or not the mastoid and sinus should be explored; it should be kept in mind that all types of mastoid infection are not alike, and that some present graver risks to the patient than others. A most practical and reliable sign, if one side is thrombosed, is the production of intense and immediate headache when one compresses the opposite or normal jugular vein.

One should study the mastoid carefully at the time of operation, making all necessary exposures of sinus and dura if suspicion warrants it. A perisinus abscess without granulations on the sinus is much more to be feared than one with marked granulations which represent a good reaction on the part of nature to overcome the infection.

As soon as the diagnosis is made, the treatment is purely surgical. The first successful surgical procedure along this line was carried out by Lane in 1899. Since that time, various methods have been developed

for dealing with the sinus, but all carry out Lane's fundamental idea. Some favor ligation of the jugular vein and resection in all cases; others, only when no free bleeding is obtained from the bulb, and some ligate only. The advantage of this lies in the fact that if a clot is located in the bulb and cannot be removed at operation, one may irrigate the vein and bulb with physiologic solution of sodium chloride in order to displace the clot. Results show little difference.

My technic in ligating the jugular vein is as follows: 1. Always ligate before opening the sinus. 2. Select healthy tissue (to tie jugular). 3. Ligate above facial branch when possible. 4. If facial branch is high, tie jugular and facial vein separately. The last two steps are taken to prevent collateral circulation.

It seems unnecessary to deal with the treatment of the sinus itself, as almost every one follows the same cardinal principles.

One should use as little pressure and packing as possible in order to obtain hemostasis. Optic neuritis has followed operation for lateral sinus thrombosis, and it is a question whether the neuritis is really due to the obstruction of the vessel or to pressure against the brain.

Prognosis: A number of patients with lateral sinus thrombosis recover spontaneously, and the condition is not diagnosed. The prognosis is good when the tongue is moist and not very coated, and when the temperature comes down by lysis after operation. If the temperature returns to normal the first day after operation, and if the ratio between temperature and pulse is abnormal, the prognosis is poor. One should always be on the lookout for an infected clot when pressure has been made with plugs instead of a sterile clot which should be there. This is because the operator does not get around the phlebitis entirely, and the two walls of the vein are infected.

*Abscess of the Brain.*—This condition comprises from 2 to 3 per cent of the intracranial complications; from 60 to 70 per cent of the abscesses occur in the temporosphenoidal area; from 20 to 25 per cent in the occipital region, and from 10 to 15 per cent in the cerebellum.

Etiology and Pathology: Chronic purulent otitis media produces far more abscesses of the brain than acute purulent otitis media, and also more cerebellar abscesses in proportion. Streptococcus is the most common organism. Any germ in acute purulent otitis media may cause an abscess. A pure culture is more frequent than a mixed one. The classification, limitation and structural arrangement of abscesses of the brain depend on the texture of the brain substance and the mode of entrance of the infection. The direct spread of the infection up through the tegmen tympani causes the greatest number of temporosphenoidal abscesses, while the majority of cerebellar abscesses are thought to be embolic in origin, the infection being carried through the blood stream.

As a general rule, the majority of abscesses are situated near the diseased area of bone forming the immediate pathway of intracranial infection. In a minority of cases, however, a considerable distance intervenes between the osseous lesion and the resulting abscess. An infection of the middle ear may entirely heal before symptoms of an abscess appear. And the latter, having become encapsulated, may remain absolutely without symptoms for many months.

Diagnosis: A large number of these patients are moribund when first seen. Therefore, it is a difficult and many times an impossible task to make any diagnosis. The localization is inaccurate, and the data obtained questionable. The vital point to be determined is the presence of an intracranial suppuration in its early stage before evidence of compression has become manifest.

Headache is perhaps the most common symptom. It may be dull or acute, local or general, on the same or the opposite side of the aural infection. The temperature is usually subnormal. It may be normal, however, or rise extremely high at one point and then drop again, producing a characteristic curve. The pulse and the respiration are slow at first, but may be fast in the terminal stages. The patient frequently complains of being chilly, but definite chills do not occur as in sinus thrombosis.

Vomiting is a characteristic sign. It is projectile in type, bearing no relation to the intake of food. It is intermittent and not severe at the onset, making one think it is due to diet. In children convulsions are frequent although infrequent in adults.

When pressure symptoms predominate, the senses become blunted, cerebration is slow, the latent period is increased and the mind is dull. Later, periods of alertness and clearness of mind alternating with unconsciousness appear, as well as stupor, incontinence, coma and respiratory failure.

Optic neuritis is an important confirmatory sign, but its absence does not rule out abscess. This develops sooner and is more severe in infections of the posterior fossa than in those of the middle or anterior fossa. It is rarely followed by atrophy if the pressure is relieved.

One of the characteristic symptoms of a developing abscess is the progressive ill health shown by a coated tongue and a loss of appetite and weight. The last two symptoms are especially marked in a lesion of the cerebellum.

The localization of an abscess of the brain in obscure cases will tax the ingenuity of the best clinician. It may not be from a lack of study and correlation of facts in a given case that an incorrect diagnosis is made. Otoscopy with functional test of the ear and comparison with clinical symptoms which can be attributed to the condition of the ear is the safest aid to a correct diagnosis. Vestibular tests are of value in

determining the presence of an intracranial involvement and whether an abscess, if present, is cerebellar or temporosphenoidal. As intradural suppuration does occur without indicative manifestations, it is a wise precaution to determine the labyrinthine reactions prior to all operations on the mastoid, as sometimes the Bárány tests give the only clue to an intracranial lesion. If this reaction is normal, the abscess is more than likely in the temporal lobe, while if the labyrinth is involved, the abscess is in the cerebellum. This is more likely if the patient presents a staggering gait and projectile vomiting.

A characteristic symptom of a cerebellar abscess is nystagmus which is not continuous, and which changes its direction frequently and is sustained. The patient will fall toward the affected side, and this phenomenon is not changed by altering the position of the head. Vertigo is marked, with inability to balance and coordinate normally; falling, past pointing, ataxia, loss of muscle tone and intention tremor are common. Dysdiadokokinesia and paralysis of the muscles of the face and extremities on the same side as the lesion are frequent. Marked deafness occasionally occurs, indicating involvement of opposite auditory tracts by pressure. Rotary nystagmus toward the affected side plus a dead labyrinth, a slow pulse and low temperature, and often optic neuritis are practically always indicative of a cerebellar lesion.

Kerrison<sup>7</sup> stated that recurrent vomiting with vertigo, rotary nystagmus and nausea, the symptoms showing signs of abatement, is characteristic of labyrinthitis. If no nausea is present and the symptoms increase, the lesion is probably a cerebellar abscess.

Temporosphenoidal abscesses are much more common than cerebellar, the ratio in children being quoted as around six or seven to one and in adults about two to one. The presence of an aphasia, pupillary changes in the eye corresponding to the same side of the suspected abscess, and contralateral paralysis, pronounced in the face, arm and hand, but slight or absent in the lower limb, along with the other symptoms common to both lesions, point strongly to a temporosphenoidal lesion.

**Differential Diagnosis:** Incipient polyencephalitis, acute toxic meningo-encephalitis, brain tumor and diffuse suppurative labyrinthitis are perhaps the most common conditions for which an abscess of the brain may be mistaken. Without the presence of focal symptoms, the diagnosis is difficult.

The treatment is surgical, and its purpose is to evacuate pus and establish drainage. Even with this accomplished there are many dangers

---

7. Kerrison: *Diseases of the Ear*, Philadelphia, J. B. Lippincott Company, 1923.

to be considered, namely: (1) meningitis, (2) hernia of the brain and (3) dissemination of infection.

Cahill<sup>8</sup> attempted to produce protective adhesions of the pia-arachnoid prior to the dural incision and later established drainage by the Mosher wire gauze cone sutured into the dural opening.

Dowman<sup>9</sup> advocated the induction of protective adhesions between the cortex of the brain and the dura before the establishment of drainage.

King<sup>10</sup> created a large cranial defect directly over the abscess cavity, with "unroofing" of the cavity and complete herniation or eversion of the same. He then treated the involved area by irrigating with a solution of chlorinated soda.

When one is so fortunate as to find a dural fistula and pus is seen escaping therefrom, no attempt should be made to enlarge the dural opening, because these fistulous tracts may be depended on to maintain adequate drainage. The proof of this lies in the fact that the large majority of patients in these cases recover.

Prognosis: A mortality rate of 40 per cent or more gives any case of abscess of the brain, to begin with, a grave prognosis. One should always consider the prolonged convalescence and the dangers accompanying the same before expressing too much optimism over the outlook. The cases in which there is no relief following surgical intervention usually terminate fatally.

*Meningitis.*—The frequency of meningitis is from 5 to 7 per cent.

Etiology: The etiology is practically the same as that in sinus thrombosis and abscess of the brain.

Pathology: Kerrison's classification of meningitis is as follows: (1) pachymeningitis, (2) serous meningitis, (3) circumscribed purulent leptomeningitis and (4) diffuse purulent leptomeningitis. The first two are local, the third gives a sterile culture or few organisms and the fourth shows numerous organisms and is nearly always fatal.

Pachymeningitis is characterized by circumscribed areas of dura being thickened, congested and covered with granulations. This is frequently found in extradural abscesses and often not suspected before operation. It does not prove serious unless neglected, and surgical treatment is the only rational one.

Serous meningitis may be secondary to pachymeningitis and also may complicate an extradural abscess. The arachnoid and pia mater

8. Cahill: Tr. Am. Otol. Soc. 17:42, 1925.

9. Dowman, C. E.: The Treatment of Brain Abscess by the Induction of Protective Adhesions Between the Brain Cortex and the Dura Before the Establishment of Drainage, Arch. Surg. 6:747 (May) 1923.

10. King, J. E.: Treatment of Brain Abscess, Arch. Otolaryng. 1:26 (Jan.) 1925.

are congested and edematous, but have escaped actual infection. Pus and bacteria are not present in the spinal fluid.

Circumscribed purulent leptomeningitis denotes a suppurative inflammation involving the arachnoid and pia mater over a limited area. The extension of the process has been walled off by nature's effort to overcome the infection. Lumbar puncture, however, may reveal fluid containing pus and bacteria.

Diffuse purulent leptomeningitis is a suppurative inflammation of the meninges which has reached the subdural and subarachnoid spaces, involving the arachnoid and pia mater, and spreading widely with no tendency to limitation on the part of nature.

Diagnosis: The diagnosis of meningitis is not so difficult as that of sinus thrombosis or abscess of the brain. The majority of cases, especially those of diffuse purulent leptomeningitis, are well defined and present a clearcut picture.

The patient is always extremely restless, complains of a severe headache and is never contented. Carphologia is characteristic, and it is difficult to keep covering over the patient's body. The temperature is high and continuous, and the pulse rate depends on the stage of the disease. Reflexes are increased at the beginning and decreased or absent in the last stage.

Rigidity of the muscles of the back of the neck usually appears on the second or third day, and sooner or later photophobia becomes a prominent symptom. In the final stage, the mental condition changes from one of extreme restlessness to delirium. Changes in the pupils and eyegrounds are common. The blood count is always high, showing a leukocytosis with a high percentage of polymorphonuclears. Lumbar puncture may show a cloudy spinal fluid with the presence of pus and bacteria and a decrease or absence of sugar before any of the clinical symptoms appear. Therefore, in any suspected case of meningitis, this procedure should be always carried out before a definite conclusion has been reached, as it may furnish the only reliable data as to the nature and gravity of the lesion.

Treatment: In cases of meningitis which are otitic in origin, surgical treatment should be instigated as soon as possible. Thorough removal of all diseased structures contiguous to the meninges with free exposure of the adjacent dura will usually suffice in the first three types of cases. If this operation does not bring about prompt relief from the meningeal symptoms, then the dura should be incised.

For cases of diffuse purulent leptomeningitis no satisfactory treatment has been found. There have been a few recoveries reported, most of them obtained by frequent lumbar or cisternal punctures. Of late, continuous drainage of the spinal cord by the removal of a lamina and the insertion of a drain has been advocated.

Prognosis: In types 1 and 2 the patients usually recover, provided they receive prompt and proper attention; in types 3 and 4 the prognosis is grave, and only about 1 per cent or less of the patients recover. Circumscribed leptomeningitis is usually the precursor of diffuse purulent leptomeningitis, and after the former has been converted into the latter, death nearly always results, no matter what the treatment may be.

#### CONCLUSIONS

During the past few decades, intracranial complications arising from purulent otitis media have taken a front rank in the realm of medicine. Owing to a lack of knowledge concerning fundamentals governing them, this group of cases at first did not receive the detailed study necessary to accomplish a great deal. Review of the recent literature, however, shows much progress in the diagnosis, treatment and management of sinus thrombosis and abscess of the brain, but little, if any, in meningitis.

From the statistics published in this paper, one will readily notice that the frequency of intracranial complications from purulent otitis media is far greater than the average physician realizes, and every abscessed ear, whether the condition is acute or chronic, should receive constant and accurate attention, which means that the patient should be directly under the observation of a specialist.

# JOHN BROWN ON MEDICAL EDUCATION\*

JEROME R. HEAD

The present system of medical education has many virtues, and many of its evils are inherent in the variable natures of individual students and professors. The four years of preclinical study make certain that the students are exposed thoroughly to the sciences that are the foundation of the profession. If it is complained that these subjects are taught by men who know little of practical medicine, it can be said with equal justice that for this reason they are probably taught with greater thoroughness. And to those who say that it is absurd to spend four years on these and then but two on the art that is so long to learn, it can be answered that the students will spend the rest of their lives in acquiring clinical experience, whereas but few will refer again to their preclinical textbooks. In defense of his lectures, quizzes and cramming, the clinical man can justly say with Lord Granville that medicine is a large and difficult subject and that somehow or other the field must be covered and the student be made acquainted, at least by name, with much that he may later encounter intimately.

In spite of these virtues and these arguments, there is general dissatisfaction with the existing curriculum, and it is the belief of many that it can be changed for the better without slighting the basic sciences, rather with teaching them to better advantage, and without passing over ground that should be covered. The focus of criticism is on the gap that exists between the preclinical and the clinical years and on the system of teaching by book and by lecture rather than by experience and example. Certainly, it is true that the first years are too purely scientific, and the last too purely clinical, and it is equally true that that which is learned at first hand is learned best. Could the sciences be taught more in conjunction with the clinical subjects and these more in the light of the sciences, and could the students spend more time in supervised activity in the wards and in the dispensary, it is reasonable to believe that they would be graduated, and would continue to be, more scientific and more practical physicians than they are today. There is a touch of absurdity in teaching separately these subjects that are useful only when mixed, as if a housewife instead of making a cake were to serve first the flour, then the sugar, the eggs and so on, and expect those served to synthesize an idea of how excellent a cake she might have made of them.

---

\* From the Department of Surgery of the Medical School of the University of Illinois.

Because so many of his remarks are pertinent to these problems, it has seemed worth while to call the attention of those interested to the writings of John Brown of Edinburgh. A product of the older practical curriculum and the apprentice system and a witness of the growth of the sciences and their entrance into the courses, he was in an excellent position to note the effects of the changes; and, being by choice and talent a writer as well as a physician, he could tell effectively of what he had observed.

John Brown was born in Scotland in the year 1810. Descended from three generations of country preachers, he escaped the family calling, and studied medicine in Edinburgh. For a time he was a student and assistant of Syme's, but later, staying in Edinburgh, he took up the practice of general medicine. In his spare hours, he wrote essays, and it is for these chiefly that he acquired fame in his lifetime and that he has been remembered since. His practice, perhaps because he was too successful as a writer, was never large. His essays need not be apologized for as the works of a physician. He was the friend of Ruskin, Carlyle, Holmes and many other men of letters in his and other countries. Although he is known chiefly as the author of "Rab and His Friends," his miscellaneous essays, medical, and on men and the arts, are no less excellent. Without attempting to describe the qualities that made him great, I will say merely that, as he was one of the few practicing physicians who wrote well on medical and other subjects, his works should be read by all men of medicine. He died in 1882 at the age of 72.

In the first volume of "Spare Hours," and especially in the introduction and the essay on Locke and Sydenham, he set forth his ideas on medical education. The tenor of these can be judged from the following paragraph in the introduction in which, speaking of his essays, he said:

If they are of any use, it will be in confirming in the old and impressing on the young practitioners of the art of healing, the importance of knowledge at first hand; of proving all things and holding fast only that which is good; of traveling through life and through its campaigns, as far as can be, like Caesar—*relictis impedimentis*—neither burdened over much with mere word knowledge, nor led captive by tradition and routine, nor demoralized by the pestilent lusts of novelty, notoriety, or lucre.

In the face of the rising tide of science, he emphasized the fact, then and even now a bit likely to be forgotten, that much of medicine is and must always be an art. In his own words, he "iterated and reiterated the necessary differences between speculative science and practical art and championed what Sydenham called 'the ancient and serious diligence of Hippocrates' and the necessity of learning of disease by dealing with it." "We are nowadays," he said, "in danger of neglecting the art in mastering our science, though medicine in its ultimate resort must always

be more of an art than a science." The following passage which he quoted from Sydenham should be set above the portals of all schools of medicine :

Having returned to London, I began the practice of medicine, which, when I studied curiously and with most intent eye and utmost diligence, I came to this conviction, which to this day increaseth in strength, that our art is not to be better learned than by its exercise and use, and that it is likely in every instance to prove true, that those who have directed their eyes and their minds the most accurately and diligently to the phenomena of disease will excell in eliciting and applying the true indications of cure.

Of Sydenham, he wrote :

He is constantly inculcating the necessity of getting our diagnostic knowledge at first hand, ridiculing those descriptions of disease which the manufacturers of "bodies of Medicine," "Hand Books," and such like, make up in their studies, and which are oftener compositions than portraits, or at the best bad copies and which the young student will find it hard enough to identify in real life. There is too much of this we fear still; and Montaigne, who rejoices at a sly hit at his cronies, the doctors, might still say with some reason, "Like him who paints the sea, rocks, heavens, and draws the model of a ship as he sits safe at his table; but send him to sea, and he knows not how or where to steer; so doctors oftentimes make such a description of our maladies as a town crier does of a lost dog or donkey, of such a color and height, such ears, etc.; but bring the very animal before him and he knows it not for all that."

Not only did he think that much of medicine can be learned best at first hand, but he believed that it cannot be learned otherwise. Again speaking of Sydenham, he said :

His inborn gifts and much of what was most valuable in his experience were necessarily incommunicable to others, this depending somewhat on his forgetting the process by which, in particular cases, he made up his mind, and its minute successive steps, from his eagerness to possess and put in action the result, and likewise from his being confident in the general soundness of his method, and caring little about formally recording to himself his transient mental conditions, much less announcing them particulary to others; but mainly, we believe, because no man can explain directly to another man how he does any one practical thing, the doing of which he himself has accomplished, not at once, or by imitation, or by teaching, but by repeated personal trials by missing much before ultimately hitting.

In the same vein he continued :

You may be able to expound excellently to your son the doctrines of gunnery, or read him a course of lectures upon the principles of horsemanship, but you cannot transfer to him your own knack as a dead shot or make him keep his seat over a rasping fence. He must take pains to learn these for himself, as you have done before him. Thus it is that much of the best of a man like Sydenham dies with him.

As to the distinction between the art and the science of medicine, he wrote :

This is what makes medicine so much more of an art than a science and dependent so much more upon the agent than upon his instructions, and this it is that makes us so earnest in our cautions against the supposition that any amount of scientific truth, the most accurate and extensive, can in medicine supercede the necessity of the recipient of all this knowledge having, as Richard Baxter says, by nature "a special sagacity," a naturally searching and conjecturing turn of mind. Moreover this faculty must be disciplined and exercised in its proper function, by being not only a hearer, but also a doer, an apprentice as well as a student, and by being put under the tutorage of a master who exercises as well as expounds his calling.

This subject of art and science [he said] is hinted at with his usual sagacity by Plato in a singular passage in his *Theaetetus*: "Particulars," he said, "are infinite and the higher generalities give no sufficient direction in medicine; but the pith of all sciences, that which makes the artsman differ from the inexpert, is in the middle propositions, which, in every particular knowledge, are taken from tradition and experience."

Explaining this, or, as he said, "treating it exegetically," the author, that is, John Brown, wrote:

Scientific truth is to the mind of the physician what food is to his body; but in order to keep his mind being nourished and growing by this food, it must be assimilated—it must undergo a vital internal change—must be transformed, transmuted and lose its original form. This destruction of former identity—this losing of itself in being received into the general mass of truth—is necessary in order to bring abstract truth into the condition of what Plato calls the "middle propositions," or, as Mr. Mill calls them, "the generalities of knowledge." These are such truths as have been appropriated and vitally adopted by the mind, and which, to use Bacon's strong words, have been "drenched in flesh and blood," have been turned "in succum et sanguinem."

Of the manner of acquiring this true knowledge, facts "drenched in flesh and blood," he wrote:

And every man who is in earnest, who looks at nature and his own proper work with his own eyes, goes on through life demolishing as well as building up what he has been taught and what he teaches himself, he must make a body of medicine for himself, slowly, steadily, and with a single eye to the truth. He must not on every occasion run off to his cyclopaedias, or still worse, to his manuals.

For in Physic, as in other things, men are apt to like ready made knowledge; which is generally as bad as ready made shoes or a second hand coat.

As we have already seen, he had little use for lectures, for talking of and about or for reading as the only methods of learning medicine. From this point of view, he criticized the curriculum then existing as follows:

Now everything, or at least most, is done in public, in classes, and it is necessarily with the names of things rather than with the things themselves, or their management, that the young men have chiefly to do. The memory is exercised more than the senses or the judgment; and when the examination comes, as a matter of course the student returns back to his teacher as much as possible of what he has received from him and as much as possible in his very words. He

goes over innumerable names. There is little opportunity even in anatomy for testing his power or his skill as a workman, as an independent observer and judge, under what Sir James Clark justly calls "the demoralizing system of cramming." He repeats what is already known, he is not able to say how all or any of his knowledge may be turned to practical account. Epictetus cleverly illustrates this very system and its fruits. "As if sheep, after they have been feeding, should present their shepherds with the very grass which they had cropped and swallowed, to show how much they had eaten, instead of concocting it into wool and milk."

Of the results of this system, he drew an amusing picture. "Often," he said, "when I see some of our modern Admirable Creightons leaving their University armed cap-a-pie, and taking the road where they are sure to meet with lions of all sorts, I think of King Jamie in his full armor. 'Naebody daur meddle wi' me' and, with a helpless grin, 'I daur meddle wi' naebody.'" And he contrasts the product of the schools with "the raw prentice lad whom Gideon Gray had sent up from Middlemas to the head of Caddon Water to deliver the herd's wife, and who, finding her alone and sinking from uterine haemorrhage, and having got the huge flaccid deadly bag to contract once more, imprisoned it in a wooden wicker or bowl, with a tight binder over it, leaving his hands free for other work. This rough and ready lad has probably more of the makings of a village Abercrombie than the pallid and accomplished youth who is spending his holidays at the next farm, and who knows all for and against Dr. R. Lee's placental and cardiac claims, and is up to the newest freak of the Fallopian tubes and their fimbriae, or the very latest news from the ovisac and the corpora lutea."

The practice of medicine is not a thing of books and of laboratories, and he questioned the value of the cramming system in preparing men for this profession "where you must mend your watch while it is running, must shoot your game on the wing."

"To be sure," he said, "there may be boys who can know everything, and do the one thing that is needed, but the mental faculties, or capacities rather, that are cultivated and come out strong in the cramming system, are not those on which we rely for safe, ready and effectual action."

The solution of the problem is suggested in its statement. If medicine is to be learned only in the doing, then by all means the students should be allowed to do. "And here it is," he said, "that we have given up the good of the old apprenticeship system, along with its evil. This will remedy itself. The abuse of huge classes of mere hearers of the law, under the professor, has gone, I hope, to its utmost, and we may now look for the system breaking up into small bands of doers acting under the master, rather than multitudes of mere listeners, and not unoften sleepers."

In another place, he spoke a good word for the "old 'prentice system'."

We have often thought that the apprenticeship system is going too much into disrepute. It had its manifest and great evils; but there was much good got by it that was not to be got in any other way. The personal authority and attachment, the imitation of their master, the watching his doings and picking up odds and ends of his experience, the coming under the influence of his mind, following his steps, looking with his eyes and unconsciously accumulating a stock of knowledge, multifarious though it might be, the good of which was not fully known until after years explained and confirmed its worth.

He quoted an imaginary picture of the curriculum that would have been prescribed by the old masters. "Had the office of settling the kind and amount of medical education been committed to Gregory, and Heberden, and Baillie, they would, I am persuaded have made the indispensable subjects of education very few, and the lectures very few too. "They would have made the attendance upon the sick in the hospitals a constant, systematic, and serious affair."

From the foregoing quotations, one might justly conclude that the author would not find any room for the sciences, that he regarded them as unnecessary ornaments. This is not the case. If he gave this impression, it was merely that he was championing a waning cause. The sciences, he knew, did not lack praising; the art, he felt, did. That he did value them and that he did believe they should be taught thoroughly, but that he believed, as many do nowadays, that they were not taught sufficiently in their application, is evidenced by the following passage:

In this intensely scientific age we need some wise heads to tell us what not to learn or to unlearn. Let us by all means avail ourselves of the unmatched advantages of modern science and of the discoveries which are everyday multiplying with a rapidity that confounds, let us convey into and carry in our heads as much as we safely can of new knowledge from chemistry, statistics, the microscope, the stethoscope, and all new helps and methods; but let us go on with the old serious diligence—the experientia as well as the experimenta. Let us look with our own eyes and feel with our own fingers. . . . The great problem in the education of young men for the practice of medicine in our times, is to know how to make the infinity of particulars, the prodigious treasures of mere science, available for practice—how the art may keep pace with and take the maximum of good out of the science. . . . We are now in our plans of medical education aiming too much at an impossible maximum of knowledge in all, meanwhile missing greatly that essential minimum in any which, after all, is the one thing we want for making a serviceable staff of doctors for the community. When too much is exacted, too little will be learned.

Thus, he was doubtful whether or not the science should be taught as if each student were to be a research chemist, a histologist or a pharmacist. He said:

It is the remark of a profound thinker that all professional men labor under a great disadvantage in not being allowed to be ignorant of what is useless; everyone fancies that he is bound to receive and transmit whatever is believed to have been known. And it seems to be a wise and benevolent, though by no means an obvious

arrangement of a Creative Providence that a certain degree of oblivion becomes a most useful instrument in the advancement of human knowledge.

On this subject, he concluded in his original vein :

Our ordinary senses, our judgment, and our law of duty, must make up the prime means of mastering and prosecuting with honor and success the medical, or indeed any other profession founded upon the common wants of mankind.

Microscopes, pleximeters, the nice tests of a delicate chemistry, and all the transcendental apparatus of modern refinement, must always be more for the few than the many. Therefore it is that I would insist more and more on immediate, exact observation and individual judgment as the mainstays of practical medicine. From the strenuous, life-long, truth-loving exercise of these let no amount of science, however exquisite, decoy the student ; and let him who has them not, greatly long after, as he will greatly miss, these higher graces of the profession.

What would be the function of the teacher in a curriculum of the kind suggested can be surmised from what has already been said. Certainly he would not be the lecturer, the reader of the law, "to mere listeners and not unoften sleepers;" and he would not be the lord high director of cramming, or the shepherd who received back from his sheep the undigested hodge-podge he had fed them. Rather would he be like Locke and Sydenham who "professed to be more of guides than critics and were the interpreters and servers of nature, not her diviners and tormentors. They pointed out a way and walked in it; they taught a method and used it." He would be like Dr. Latham who "in leading his pupils into the wards of St. Bartholomew's made the following beautiful remark: 'In entering this place, even this vast hospital, where there is many a significant, many a wonderful thing, you shall take me along with you and I will be your guide. But it is by your own eyes and your ears and your own minds, and (I may add) by your own hearts, that you must observe, and learn, and profit. I can only point to the objects and say little else than see here, and see there.'"

The school then would be composed of groups of doers under the master, and the master would teach clinical methods and a scientific point of view and would consider it more worth while to arouse curiosity than to impart facts. He would teach by example and direction, and would be one to be consulted and questioned. If he himself asked questions it would be not to quiz, but rather in the spirit of Socrates, to stimulate the student to think for himself and to think reasonably. If he succeeded in imparting a method and a point of view and in arousing curiosity, he would be content, knowing that his students, after they left school, would go on learning for themselves and would be in a way, eventually, to become good physicians.

As the sciences grow and the courses increase in number, other subjects are being crowded from the curriculum. There is no longer any time for literature or the arts, much less for Greek or for more Latin

than is required. The cry is for more science in a shorter time, and the other courses are considered ornaments that can be dispensed with. To omit the author's ideas on this subject would be to pass over an important aspect of his thoughts on medical education. They are expressed in the following passage, which he quoted from Dr. Latham :

I wish to see physicians still instituted in the same discipline and still reared in fellowship and communion with the wisest and best of men, and that not for the sake of what is ornamental merely, and becoming to their character, but because I am persuaded that that discipline which renders the mind most capacious of wisdom and most capable of virtue, can hold the torch and light the path to the sublimest discoveries in every science. It was the same discipline which contributed to form the minds of Newton and of Locke, of Harvey and of Sydenham.

In the foregoing quotations, there are few ideas that are new ; and, I daresay, in gatherings of medical educators, many of them are truisms. Yet a glance around will convince any one that they are not yet sufficiently learned, and, therefore, that even today the author would have been justified in iterating and reiterating the necessary difference and the regrettable gap between the art and the science of medicine.

I will close by expressing the hope that these quotations may stimulate some to make or to remake the acquaintance of this Scotch physician who, like Oliver Wendell Holmes, Weir Mitchell and a few others, was a contributor to two arts, medicine and literature.

# PYELITIS, URETERITIS AND CYSTITIS CYSTICA

REPORT OF A CASE SHOWING UROGRAPHIC EVIDENCE OF THE  
LESION IN THE URETERS AND PELVES \*

JAMES J. JOELSON

Pyelitis, ureteritis and cystitis cystica is a condition characterized by the presence of numerous small cysts of the mucous membranes of the urinary tract. The lesion may be limited to the bladder, but frequently it is found to be present also in the ureter and renal pelvis. Bullous edema of the bladder may sometimes resemble or be confused with cystitis cystica, but in the latter condition the cysts practically always have a definite epithelial lining (Young).

Probably the first description of this condition was made by Morgagni in 1761. Since then, many articles on the subject have appeared. The lesion is usually found to be associated with a chronic inflammatory condition of the urinary tract, and several views have been put forth as to the origin of the cysts. Virchow, in his case report, suggested that the cysts might be caused by blocking of crypts in the mucosa of the ureter. Several other observers have expressed the opinion that the cysts were the result of an inflammatory blocking of preexisting mucous glands and crypts of the mucous membranes of the urinary tract (Litten), but although preexisting glands have been described (Egli, Hamburger) they are by no means constant structures. The view that the cysts were of parasitic origin has also been expressed (Bland-Sutton, Eve, von Kahlen, Morris, Pisenti and Voelker).

The most generally accepted theory is that put forth by von Brunn in 1893. He suggested that inflammation of the urinary tract at times caused downward proliferation of the epithelium which he termed epithelial buds or sprouts. Frequently the epithelial connection between the surface epithelium and the buds disappeared resulting in small groups of epithelial cells lying below the mucous membrane; these groups of cells he called epithelial nests. Von Brunn thought that by the degeneration of the central cells of these small groups of cells cysts were formed.

Many authors have published articles in which they have agreed, some with minor variations, with von Brunn's views (Aschoff, Harris, Jacobson, Liebreich, Lubarsch, Morse, Motz and Cariani, Radtke and Saltykow). Herxheimer stated that the cell nests in which the cysts originated might follow an inflammatory process or might be caused by the elimination of toxic substances. In this way he explained Marck-

---

\* From the Department of Surgery of the Lakeside Hospital and the Western Reserve University School of Medicine.

Fig. 1—Cystoscopic view of the trigone, showing the numerous small cysts scattered over the surface.

Fig. 2.—Low power magnification of biopsy specimen, showing cluster of small cysts partially covered on one side by bladder epithelium;  $\times 40$ . Both colloid and purulent cystic contents are seen, and there is a diffuse inflammatory infiltration of stroma.

wald's case in which that author described ureteritis and cystitis cystica in a new-born infant. Stoerk agreed with von Brunn as to the origin of the cell nests but considered the formation of the cysts to be due to a secretion of the cells rather than a degenerative process.

Giani has produced cystitis cystica experimentally in rabbits by the irritation of a foreign body in the bladder and by curetting the vesical mucosa through a suprapubic cystotomy.

Fig. 3.—High power magnification, showing (a) a small epithelial lined space which showed no communication with the surface in the serial sections, (b) an epithelial lined crypt which did communicate with the surface in the serial sections, (c) a larger cyst filled with clear acidophilic colloid material and (d) a flattened layer of epithelial cells lining colloid filled cyst;  $\times 120$ .

Morse has recently reviewed the literature and has carefully studied the urinary tracts of 125 consecutive cases in which necropsies were performed. He concluded that cysts of the urinary tract were formed from the epithelial nests of von Brunn by a process of central degeneration rather than secretion, that the epithelial buds and cell nests of von Brunn were inflammatory in nature but could be found microscopically

in the majority of persons over 20 years of age, and that epithelial buds, cell nests and cysts were not normally found in the urinary tract.

Numerous reports of cases of cystitis, ureteritis and pyelitis cystica have appeared in the literature, but a review of those articles which were available revealed no instance in which the diagnosis of the lesion in the renal pelvis or ureter was made by the pyelogram or ureterogram. Neither do the textbooks on urology or pyelography mention this possi-

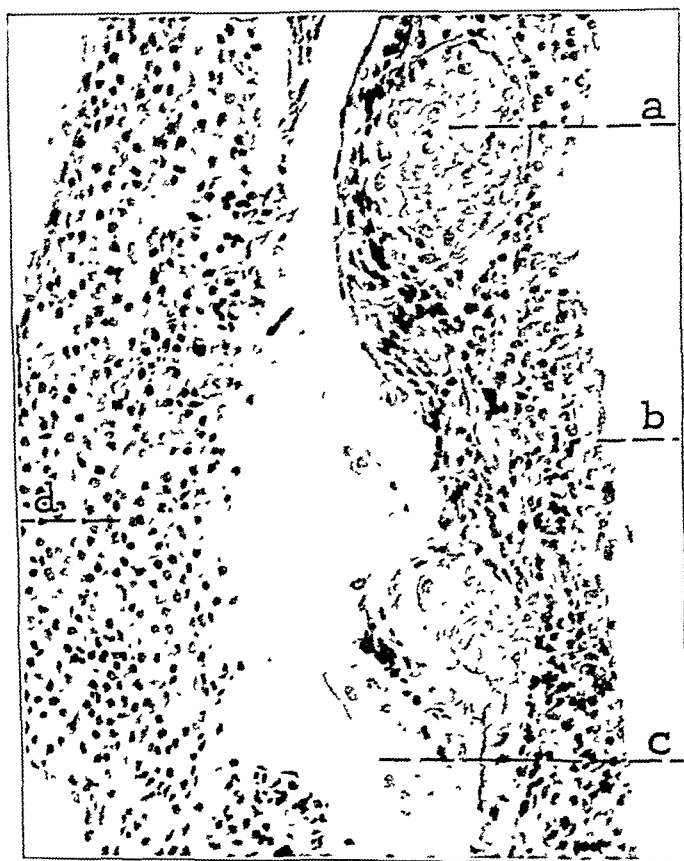

Fig. 4.—High power magnification, showing (a) solid nest of epithelial cells which were found by serial sections to be the tip of an epithelial lined crypt, (b) small fragment of surface epithelium, (c) epithelial lined crypt and (d) lymphocytic infiltration of stroma;  $\times 120$ .

bility. Since my case presents such definite urographic evidence of ureteritis and pyelitis cystica, it seemed desirable to report it.

#### REPORT OF A CASE

*History.*—J. B., a married Italian woman, aged 44, came to Lakeside Hospital on Sept. 11, 1928, because of hematuria. Her past history was essentially negative, as was also her family history. She had had four pregnancies.

Fig. 5—High power magnification, showing (a) epithelial lined space beneath surface epithelium. It is lined by cuboidal epithelium and did not communicate with the surface in the serial sections, (b) small cyst containing a mixture of colloid material and cellular debris lined by flattened epithelium and (c) cuboidal epithelial lining of large pus filled cyst;  $\times 120$

Her present illness began about thirteen years before admission when she first noticed some blood in her urine. Since then there had been repeated attacks of hematuria but these were always transient and came on at rather long intervals. For many years she had been troubled with nocturia (twice a night) and frequency. There had been no dysuria except during her pregnancies when the nocturia and frequency also became more marked.

Fig. 6—Roentgenogram, showing the shadows of calculi in both kidneys.

About a week before admission to the hospital, she was suddenly seized with a severe abdominal pain, chills and fever which lasted for about a day. The pain was most marked in the right lumbar region and was associated with gross hematuria. These acute symptoms lasted only a few days. There was no typical radiation of the pain nor any nausea or vomiting.

*Physical Examination.*—The physical examination revealed a somewhat obese, well developed woman who did not appear acutely ill or in any pain. The results

Fig 7—Right pyelo-ureterogram and left pyelogram. Numerous small areas of decreased opacity can be seen in both pelves and are probably filling defects caused by the multiple cysts. Several filling defects can also be seen in the dilated right ureter. The insert is a semidiagrammatic drawing to accentuate the small filling defects which were noted in the negative.

of the general physical examination were entirely negative. The abdominal examination showed neither kidney to be palpable, but there was slight tenderness in both costovertebral angles and in the suprapubic region.

*Laboratory Observations.*—Repeated urinalyses showed the urine always to be slightly hazy. The reaction varied, at times being acid and at other times being alkaline. The specific gravity varied between 1,006 and 1,018. Occasionally a faint trace of albumin was found. Sugar was never present. Microscopic examinations showed many pus cells to be present on all examinations, and on several occasions many red blood cells were found. The blood count showed 90 per cent hemoglobin, 4,500,000 red blood cells and 9,000 white blood cells. The Wassermann reaction of the blood was negative. Blood urea was 26 mg. per hundred cubic centimeters. Phenolsulphonphthalein test showed 75 per cent of the dye to be excreted in two hours and ten minutes.

Roentgenograms of the urinary tract showed shadows of increased density which suggested multiple calculi of fairly large size in both kidneys. The location of these calculi seemed to be in the calyces of the kidneys rather than in the pelves (fig. 6).

*Cystoscopic Examination.*—The instrument was introduced easily into the bladder. The vesical capacity and tone were normal. The entire bladder seemed to be normal except for the region of the trigone. Situated just in front of the right ureteral orifice was a small, yellowish, egg-shaped tumor mass about 4 mm. in diameter which seemed to be definitely pedunculated. In front of the left ureteral orifice there was another small pedunculated cystic tumor about 5 mm. high and about 4 mm. in diameter. Scattered over the trigone were numerous small cysts, some of which were semispherical and others oval. None of these small cysts showed the pedunculation described for those situated near each ureteral orifice. The cysts varied from 2 to 4 mm. in diameter. Toward the central portion of the trigone there was an area where many of these cysts were agglomerated and had the appearance of bullous edema (fig. 1). By means of cystoscopic rongeurs, the small, yellowish tumor just in front of the right ureteral orifice was totally excised for microscopic examination, and a piece of the pedunculated tumor from the left ureteral orifice was also removed for microscopic examination. The pathologic report of these biopsies follows:

"Histologic Examination: Serial sections of the biopsy, removed from the neighborhood of the right ureteral orifice, stained with hematoxylin and eosin, show it to consist of a cluster of small, varying sized cysts. The cysts approximate one another closely with a scanty intervening stroma of fibrous connective tissue which is the seat of a diffuse infiltration of lymphocytes and polymorphonuclear leukocytes. One surface of the biopsy is partially covered by a layer of stratified columnar epithelium (fig. 2).

"Beneath the surface epithelium are a number of small epithelial lined spaces some of which are mucosal crypts and can be followed to the surface while others are entirely closed and correspond to the cell nests of von Brunn (fig. 3). These microscopic cysts as well as the downward extensions of the surface epithelium are lined by a single or a double layer of cells which range from cuboidal to columnar in type. They are devoid of contents except for an occasional desquamated epithelial cell. In one section a small solid epithelial cell nest is seen which on examination of adjacent sections is found to be the solid tip of an epithelial lined mucosal crypt (fig. 4).

"In addition to the described epithelial spaces and crypts, there are epithelial lined spaces some of which are filled with a clear acidophilic material resembling colloid, and others with a mixture of colloid and cellular debris. One large cyst

Fig. 8.—Ureterogram of upper left ureter, showing the numerous filling defects caused by the cysts. The insert is a semidiagrammatic drawing to accentuate the small filling defects which were noted in the negative.

Fig. 9—Ureterogram of lower left ureter, showing numerous filling defects caused by the cysts. The insert is a semidiagrammatic drawing to accentuate the small filling defects which were noted in the negative.

(3 mm. in diameter) is filled with partially degenerated lymphocytes and leukocytes and is lined by a fragmentary layer of slightly flattened cuboidal epithelial cells (fig. 5). The more purely colloid the contents of the cysts are, the greater is the flattening of the lining epithelium, and in some of the cysts containing only translucent acidophilic material, the lining epithelium is not recognizable. There is no relation between the size of the cyst and the cyst contents nor is the size of the cyst reflected by the character of the lining epithelium.

"Sections of biopsy removed from the bladder near the left ureteral orifice show it to consist of a few small folds of bladder mucosa covered by stratified squamous epithelium. In places there is rather marked epithelial hyperplasia and the entire underlying fibrous connective tissue is the seat of mononuclear infiltration.

"Diagnosis: Cystitis cystica."

Several days later, another cystoscopic examination was done, and both ureters were catheterized. Several obstructions were met by the catheters on both sides, but these were all finally passed. The passage of the catheters up the ureters resulted in the escape of blood around the catheters from the ureteral orifices. A normal intermittent flow of urine was obtained from both sides. The urine from both kidneys microscopically showed pus cells and erythrocytes. One cubic centimeter of phenolsulphonphthalein given intravenously appeared from both kidneys in three minutes. The right kidney excreted 9 per cent in fifteen minutes. The left kidney excreted 8 per cent in fifteen minutes.

Cultures of the urine from the bladder, right kidney and left kidney all showed *Staphylococcus albus*.

Pyelograms and ureterograms of both kidneys and ureters were made. These showed the shadows previously noted in the regions of the kidneys to be calculi situated in the calyces. Both renal pelves were somewhat dilated. The ureters showed a rather marked degree of dilatation, and on the right side a kink was present. The pyelograms and ureterograms of both sides showed numerous small definite filling defects which were about 5 mm. in diameter, which were undoubtedly due to small cysts projecting into the lumina of the ureters and pelves. This was especially marked in the left ureter (figs. 7, 8 and 9). All pyelograms and ureterograms were repeated several times in order to eliminate the possibility that the small areas of decreased opacity were caused by air bubbles.

The patient's course in the hospital was uneventful. She had no further attacks of pain even though she was observed for a period of about two weeks. Because of the absence of symptoms and any obstruction and because of the multiplicity of the calculi, it seemed inadvisable to attempt any surgical removal of the stones.

#### SUMMARY

1. A case of cystitis cystica, bilateral ureteritis and pyelitis cystica associated with bilateral nephrolithiasis is reported.
2. The ureterograms and pyelograms gave sufficient evidence to warrant the diagnoses of ureteritis and pyelitis cystica.
3. A comprehensive bibliography is appended.

# THE RELATIONSHIP OF NONABSORBABLE SUTURE MATERIAL TO JEJUNAL ULCER

AN EXPERIMENTAL STUDY \*

W. J. MERLE SCOTT

When jejunal ulcers<sup>1</sup> began to appear as complications of gastro-enterostomy, nonabsorbable sutures sometimes were discovered in their bases. This quickly led to the assumption of a cause and effect relationship between the foreign material and the unwelcome sequel. Many papers were written on the subject, but the clinical evidence resolved itself almost exclusively to the association of the ulcer with a thread still retained. Sometimes the suture has been partially cast off but was still adherent in the region of the ulcer, or at other times a strand of thread or a knot was exposed in the base of the ulcer. But on the other hand, the retained suture frequently had no connection with the ulcer; in over one half of the cases the ulcer was away from the suture line.<sup>2</sup> The discovery of such a foreign body in the base of a jejunal ulcer was so dramatic that little thought was given to whether the nonabsorbable suture caused the ulceration or whether it was merely exposed as a result of the ulceration. As practically all gastro-enterostomies in the early decades of this operation were performed with thread of some kind, an imposing number of cases of this type was reported from various parts of the world and the sweeping conclusion was reached that *nonabsorbable sutures were responsible for anastomotic and jejunal ulcer*. Some writers went so far as to explain those ulcers which form on the wall of the jejunum opposite to the anastomosis as being due to trauma from the silk suture as it gradually worked itself loose into the lumen of the intestine.<sup>3</sup> The explanation of the traumatization of jejunal mucosa by a piece of silk thread at the most about 5 inches (12.7 cm.) long and saturated with fluid shows the fantastic extent to which at times this idea was pushed. However, the apparent causal relationship of a foreign body in the base of an anastomotic ulcer was so striking in numerous instances that most

\* From the Department of Surgery, the University of Rochester School of Medicine and Dentistry.

1. The term jejunal ulcer here and throughout this paper is intended to include both the anastomotic (gastrojejunal) ulcer and the ulcer in the jejunum distinctly separated from the gastro-enterostomy stoma.

2. Hurst, A. F., and Rowlands, R. P.: *Jejunal and Gastro-Jejunal Ulcers*, Guys Hosp. Rep. 71:319, 1921.

3. Wright, G.: *Secondary Jejunal and Gastro-Jejunal Ulceration*, Brit. J. Surg. 6:390, 1919.

surgeons believed jejunal ulcers to be due to the retained suture. This point of view was especially urged at the Mayo Clinic where it was early advocated that catgut sutures alone be used in carrying out any type of gastro-enterostomy.<sup>4</sup> And since this time, with a few exceptions, most writers on the subject have advised the avoidance of silk and linen in this operative field.

The clinical evidence, even during that period when nonabsorbable sutures were being almost exclusively used, was far from complete. Retained silk sutures were found hanging into the lumen of the intestine long after gastro-enterostomy without any ulceration.<sup>5</sup> Therefore such a retained foreign body did not necessarily result in a jejunal ulcer. Also, when ulcers did occur they were frequently found in the wall of the jejunum entirely separate from the line of anastomosis, either with or without a silk suture being retained in the latter. Consequently, jejunal ulcers were not necessarily due to a retained foreign body in the anastomosis, even when the latter was present. With the wide-spread acceptance of the insistant dictum to use catgut alone in gastro-intestinal anastomosis, came even stronger evidence that some underlying condition was the cause of jejunal ulcer and that the exposure of silk sutures in the base of anastomotic ulcers might well be the result of the ulcerative process rather than its cause. It was not many years before it became evident that the use of absorbable sutures had not prevented the occurrence of anastomotic and other jejunal ulcers,<sup>6</sup> and the hope of avoiding this complication by the choice of one suture material in preference to another disappeared. The prejudice against the nonabsorbable suture, however, remained, and the argument in favor of the absorbable suture was shifted to the position that the incidence of jejunal ulcer is not so great when catgut is used throughout as when silk or linen is employed.<sup>7</sup> Although this proposition has gained widespread acceptance, satisfactory clinical evidence supporting it is almost nonexistent. In order to be of any significance, similar series of cases of the same type in which the same operative technic was used, except for this difference in suture material, should be compared. There are scarcely any statistics of this type available. Possibly the nearest approach to this is found in the repeatedly quoted figures of the Mayo Clinic. In the first gastro-enterostomies performed in this

clinic before 1914, while nonabsorbable sutures were used, 4 per cent of the patients returned with jejunal ulcer. Since adopting absorbable sutures alone, in 8,000 gastro-enterostomies the proportion of patients returning there with jejunal ulcer is about 2 per cent.<sup>8</sup> On the face of these figures, apparently the incidence of jejunal ulcer is twice as great when nonabsorbable sutures are used as is found with absorbable sutures. However, on careful analysis, these data do not fulfill the important requirements outlined. The first series includes the patients operated on during the experimental stage of gastro-enterostomy.<sup>9</sup> In the second series, the operation had been practically standardized. Possibly, but not certainly, the types of patients in the two series were approximately the same. There probably were more gastro-enterostomies performed in the first series for conditions other than demonstrable disease of the stomach or duodenum. When gastro-enterostomy is performed under such circumstances, as Moynihan<sup>10</sup> has emphasized, one is thoroughly aware now that the results are much more likely to be unsatisfactory. Probably also, the incidence of jejunal ulcer is greater. However important this factor may be, there is positive information that during the period which includes the first series the operative technic was being varied in order to find the most satisfactory type of procedure; W. J. Mayo stated that a number of gastro-enterostomies with exclusion of the pylorus were carried out.<sup>11</sup> It is now well recognized that this combination is followed by a much higher incidence of jejunal ulcer than gastro-enterostomy alone.<sup>12</sup> Consequently, it appears to me that by a comparison of the results in the first 1,000 gastro-enterostomies done at the Mayo Clinic with those of the last 8,000, the effect of the type of suture material on the incidence of jejunal ulcer cannot be evaluated. One other clinic furnishes data on this point which are not reported numerically but in which the series are more directly comparable. In 1921, Lewisohn<sup>13</sup> reported a high incidence of jejunal ulcer following gastro-enterostomy from the surgical clinic of the Mount Sinai Hospital, and he then stated that on account of the prevalence of this serious complication a

change was being made in that clinic to the employment of catgut alone in performing gastro-enterostomy. In its bearing on the question which is being considered this was an extremely interesting experiment, especially as the operative procedure and the type of case in which this operation should be used had been well standardized for several years. The only change to be effected was the elimination of all nonabsorbable suture material in performing the anastomosis. In 1925, Lewisohn<sup>14</sup> further reported that disappointingly there had been no decrease in the incidence of jejunal ulcers from this change in suture material; and this fact was found reflected in his advocacy of gastric resection in preference to gastro-enterostomy for all forms of peptic ulcer.

One other clinical fact speaks strongly against the significance of the type of suture material in the etiology of jejunal ulcer. At first, when this complication required reoperation, most surgeons performed either a plastic operation on the stoma with excision of the ulcer, or they undid the original anastomosis and made a new gastro-enterostomy. In a great many instances, this second anastomosis was carried out carefully with catgut on account of the widespread belief that nonabsorbable sutures had caused the complication. This second gastro-enterostomy was commonly followed by a new jejunal ulcer.<sup>15</sup> When operation is necessary in a case of jejunal ulcer, nearly all authors now advise doing away with the gastro-enterostomy and either reconstituting the original gastro-intestinal pathway or performing a gastric resection. This opinion is itself strong evidence that the nonabsorbable suture material used in the first operation was not the cause of the jejunal ulcer, otherwise the formation of a new anastomosis, using catgut alone, would be a satisfactory operation to cure the complication.

Many gastro-enterostomies, either alone or combined with resection, have been carried out with nonabsorbable sutures for gastric carcinoma. Yet there is hardly an authenticated case of jejunal ulcer following such an operation for tumor. This also, as Strauss<sup>16</sup> has emphasized, speaks strongly from the clinical standpoint against the significance of the type of suture material used and as strongly in favor of the importance of the ulcer diathesis that had caused both the jejunal and the original duodenal ulcer. Bland-Sutton as long ago as 1916 expressed this same idea in the title of his Hunterian address, "Ulcers New and Old: Jejunal for Duodenal Ulcers."<sup>17</sup> At that time he concluded, "Some

surgeons attribute these secondary ulcers to faults of technique or a method of suture different from that employed by the surgeon who criticises the report. There is very little evidence available for the incrimination of silk or linen thread." This seems equally true today as no new evidence of this type has been presented in the intervening years, but the opinion that the nonabsorbable suture was responsible at least in part for jejunal ulcers has been repeated from one paper to another.

To summarize, then, the clinical data on the relationship of non-absorbable suture material used in carrying out a gastro-enterostomy to the subsequent formation of a jejunal ulcer, it appears that the evidence is not entirely decisive in all details, but it is definite that jejunal ulcers depend on some underlying condition rather than being due to retained sutures. And what little information there is on the incidence of the complication relative to the type of suture material used does not substantiate the commonly accepted view that the use of silk or linen is followed by any higher proportion of jejunal ulcers than is the use of catgut.

On account of the preference of many surgeons for the technical advantages of silk in gastro-intestinal operations, and the difficulty of being certain from the clinical evidence that nonabsorbable sutures do not tend to favor the formation of jejunal ulcers, it was decided to get, by experimental study, some further light on the influence of silk sutures in an ulcer producing environment. Mann and his colleagues have shown that chronic peptic ulcers similar both in pathologic appearance and in their natural history to those found in human beings occurred in a high proportion of dogs after drainage of the duodenal secretions into the lower ileum.<sup>18</sup> By this procedure, an underlying condition is produced which tends toward the development of a chronic ulcer of the jejunum just past the anastomosis with the stomach. If the presence of nonabsorbable suture material in the anastomosis plays any significant rôle in furthering the ulcerative process, as has been assumed by many to be the case in patients, then the ulcer which arises should occur at least in a large proportion of the cases about the retained suture. If on the other hand, as has been suggested in the foregoing analysis of the clinical data, the jejunal ulcer is dependent on some underlying condition and independent of the type of suture used, then the jejunal ulcer should arise in the usual location found by Mann and his co-workers, using catgut alone, at a point distinctly separated from the suture line.

---

18. Mann, F. C., and Williamson, C. S.: The Experimental Production of Peptic Ulcer, *Ann. Surg.* **77**:409, 1923. Morton, C. B.: Observations on Peptic Ulcer, *Ann. Surg.* **85**:207, 1927.

One other method for producing jejunal ulcer was also employed. Dott and Lim showed that gastro-enterostomy in the dog was frequently followed by a jejunal ulcer if the original operation was accompanied by complete occlusion of the pylorus.<sup>19</sup> These investigators used catgut throughout. I happened to carry out this procedure for another purpose, and in two of my cases also it was followed by a jejunal ulcer. As is my custom in all gastro-intestinal operations, both clinical and experimental, I used silk in the anastomosis and consequently these cases were added to the preceding series.

Eight dogs were operated on by Mann's method of draining the duodenum into the terminal ileum. The jejunum was anastomosed to the pylorus with silk. Six of these animals developed typical chronic jejunal ulcers seen at autopsy or at a second operation. In every case the ulcer was separated from the line of anastomosis. It usually occurred on the anterior superior surface of the jejunum at a distance of from 1 to 1.5 cm. from the anastomosis. The ulcers were found from four to ten weeks after operation. In each case silk was still present in the line of anastomosis and in no case was there any ulceration about the silk suture. Figure 1 illustrates the typically located ulcer and its entire separation from the anastomosis with the retained silk suture. In other words, my results following the use of silk for the anastomosis were exactly similar to those of Mann, Williamson and Morton who used catgut alone. Although in a high proportion of these animals chronic ulcers occurred in the jejunum, there was no tendency whatever for ulceration to occur about the silk suture.

After an ulcer had formed in the duodenum in the animal illustrated in figure 1, a secondary operation was carried out using silk for suture material. A pyloroplasty was performed considerably widening the pylorus. On exploration several weeks later, the original ulcer high up on the anterosuperior surface of the jejunum had healed and a new deep ulcer with indurated walls had formed on the mesenteric surface of the jejunum just past the anastomosis. Although the edge of this large ulcer was only 2 mm. away from the anastomotic line and a silk suture was retained in the latter at that point, there was no ulceration about the suture (fig. 2). This ulcer was located the closest to the anastomosis of any found in my animals and illustrates nicely that the retained suture does not predispose toward the formation of the ulcer about it, although an ulcer is forming only a few millimeters away from it. It also illustrates how easily the suture could be found arising from the base of the ulcer if the ulcerative process had extended a few millimeters farther.

19. Dott, N. M., and Lim, R. K. S.: Experimental Jejunal Ulcer, *Quart. J. Exper. Physiol., Suppl.* 109, 1923.

Also in the two animals which developed jejunal ulcer after gastro-enterostomy with pyloric exclusion, the ulceration occurred in the efferent limb of the loop, and in each case it was definitely separated from the line of anastomosis. Here again, although silk sutures were retained in the anastomotic line, ulceration was not produced about them, but the ulcers were exactly similar to those found by Dott and Lim when catgut was used for the anastomosis. This corresponds with a similar observation by Watts in 1903, where the ulcer in the jejunum of a dog three months after gastro-enterostomy was situated in the jejunum opposite the stoma, and the silk used for anastomosis was still present in the latter and not accompanied by any ulceration of the anastomotic line.<sup>20</sup>

Fig. 1.—Experimental chronic ulcer of jejunum in the dog eight weeks after original operation. Silk suture retained at the site of anastomosis without ulceration.

To summarize the experimental evidence which I have presented, conditions were reproduced in dogs which cause jejunal ulcers similar in pathologic appearance and in their natural history to those seen after gastro-enterostomy in man. However, it was found that the presence of silk suture material retained in the anastomosis did not affect the localization of the process. Although an ulcer formed only from 1 to 2 cm. distance from the line of anastomosis, and in one instance after a secondary operation the edge of the ulcer was only 2 mm. from it, yet in no case was there ulceration about the retained suture.

20. Watts, S. H.: A Case of Peptic Ulcer in the Jejunum of a Dog Following Gastroenterostomy, with a Review of the Cases Reported in Man, *Bull. Johns Hopkins Hosp.* 14:191, 1903.

## COMMENT

The clinical evidence shows that jejunal ulcers arise from some factor far more fundamental than the type of suture material used. The experiments which I have carried out demonstrate that even in the presence of actual ulcer producing circumstances, retained silk sutures do not cause ulceration. In 1920, Dragstedt and Vaughn<sup>21</sup> reported that the insertion of fifteen or twenty heavy silk sutures into

Fig. 2—Original ulcer healed and new one formed on the posterior surface of the jejunum just past the anastomotic line, fifteen weeks after pyloroplasty (secondary operation). Note how close the ulcer comes to the anastomosis with the retained silk suture but without any ulceration about the silk sutures.

a small area of the stomach that had been denuded of mucous membrane delayed the healing of the mucosal defect. This they considered evidence that nonabsorbable suture material favors the formation of

21. Dragstedt, L. R., and Vaughn, A. M.: Gastric Ulcer Studies, Arch Surg. 8:791 (May) 1924.

anastomotic ulcers. However, it seems rather to show that so gross an overloading of the denuded surface with foreign material results in delayed healing. Those surgeons who use silk sutures in gastro-intestinal work do so on account of definite technical advantages. A smaller strand of suture material inserted into the tissues with a much finer needle even than the present eyeless intestinal needles fastened on to a catgut strand allows more delicate workmanship. There would surely be no advantage today in the use of silk if it resulted in encumbering the tissues with a large amount of foreign material as was done in the experiments carried out by Dragstedt and Vaughn. It is now known that chromic catgut will withstand the digestive action of the intestinal contents long enough so that there is no danger of the suture line not possessing sufficient tensile strength for healing; and silk is used in gastro-enterostomy today only as a part of the plan to traumatize tissues as little as possible. It is now common laboratory experience that simple gastro-enterostomies in dogs, using silk for suture material, are not often followed by jejunal ulcer. Gronnerud's results of an opposite nature<sup>22</sup> are apparently explained by a careful analysis of his report. The series in which he used silk sutures and clamps contains the first experiments. In this series, he had an immediate mortality rate of 20 per cent with 6 per cent more fatalities from the tenth day to the time when the animals were killed. At autopsy, varying degrees of obstruction were found in 30 per cent of the animals. In the later, much more extensive series of animals in which absorbable sutures were used his immediate mortality rate was less than 1 per cent. Obviously, any series of gastro-enterostomies associated with a 26 per cent mortality rate is valueless for comparative study on account of the evident technical inadequacy shown by this mortality, and certainly cannot be compared with a second series of gastro-enterostomies in which the mortality rate was less than 1 per cent. A far more trustworthy comparison of the effect of various suture materials in simple gastro-enterostomies is found in Montgomery's work.<sup>23</sup> He attempted to produce gastrojejunal ulcers in connection with the line of anastomosis. In sixty-three dogs he succeeded in producing an indurated and well defined ulcer in four instances. In thirty-eight of the animals, silk had been used either solely or in the outer row and in twenty-five instances catgut was used alone. In three of the four anastomotic ulcers, catgut had been the only suture material whereas only one of them occurred after the use of silk for the outer row and catgut for the inner layer.

22. Gronnerud, P.: The Etiological Relations of the Sequelae to Gastro-Enterostomy, *Ann. Surg.* 66:177, 1917.

23. Montgomery, A. H.: Gastro-Jejunal Ulcer: An Experimental Study, *Arch. Surg.* 6:136 (Jan.) 1923.

The experimental evidence supplements the clinical data in drawing attention to the significance of some underlying cause in the production of jejunal ulcer and the lack of importance in this connection of the type of suture material used. It is no part of my purpose in presenting these data to influence any surgeon to change from the use of catgut to silk in the technic of gastro-enterostomy. On the other hand, there does not seem to be any convincing evidence that silk should not be used by those surgeons who feel that it has a technical advantage in this field.

#### CONCLUSIONS

1. Jejunal ulcers are not caused by nonabsorbable suture material.
2. A careful analysis of the clinical evidence does not substantiate the commonly accepted view that the use of nonabsorbable sutures increases the incidence of jejunal ulcer.
3. Under experimental conditions which induce the formation of chronic jejunal ulcers, the use of silk in the anastomosis does not predispose to the development of the ulcer about the nonabsorbable suture.
4. There is no convincing evidence, either clinical or experimental, militating against the use of nonabsorbable sutures in gastro-intestinal operations.

# THE TREATMENT OF ABSCESS OF THE BRAIN\*

KENNETH G. MCKENZIE

Life is short  
And the art long.  
The occasion instant,  
Experiment perilous,  
Decision difficult.

The foregoing aphorism of Hippocrates occupies a prominent place above the door of the Harvard Medical School and can be plainly seen from the Peter Bent Brigham Hospital. In common with many other former members of the hospital staff, I have a photographic copy of this bit of philosophy hanging in my office, as a memento of happy days spent in that institution. It may seem a far cry from this to cerebral abscess, and yet, when one is face to face with patients suffering from abscess of the brain, the aphorism seems especially applicable. How difficult, when dealing with a case to say—"This is the correct procedure"! When a patient dies, one usually feels that something different might have been done. In the succeeding pages, an attempt will be made to present some personal views that have grown out of a special interest in the subject during the past few years.

Since 1924, eleven patients with abscess of the brain have been operated on. Several others have been seen in consultation. Also, a number of cases have been observed and followed, which have been classed as "brain abscess suspects." The preparation of a paper based on this material has not been easy. There are so many controversial points that it would be a much simpler, more profitable and more pleasant task to discuss the problem from an easy chair with an interested friend on the other side of the fire. With the proper setting, a verbatim record of such a conversation should result in an interesting paper. Surely it was in some such informal collaboration that Gilbert and Sullivan planned their delightful operas.

Usually, there is no great surgical urgency in dealing with a case of abscess of the brain, and plenty of time may be taken for careful consideration of the problem. How out of place such a statement would be if one were discussing acute osteomyelitis of children, in which early diagnosis and early surgical intervention is so essential.

It is true that the early diagnosis of an abscess of the brain is desirable, but surgical treatment should be delayed until the abscess is well walled off (usually four or five weeks from the time of the initial intracranial infection). During this period of waiting, the patient must be

---

\*From the Department of Surgery, University of Toronto.

under careful observation, and drainage should be attempted earlier if marked dulness and coma develop. Furthermore, increasing experience with cases finally classified as "brain abscess suspects" has made one conservative in advising surgical intervention. A few of the more interesting case histories of this "suspect group" will be reviewed. The remainder of the paper will be based on the "verified cases," and these will be considered largely from the standpoint of treatment.

#### "BRAIN ABSCESS SUSPECTS"

*CASE 1.—Bilateral choked disks following operation for double mastoid. Exploration for abscess of the brain. Negative observations. Death.*

A girl, aged 14, had a double mastoid operation some weeks previous to the present examination. Following the operation, she was listless and pale, and had marked loss of appetite. On neurologic examination, a bilateral choking of the disks was noted, but no other positive signs could be made out. It was believed that she had an abscess of the brain. Punctures were made into both cerebellar hemispheres and both frontal lobes, with negative results. Four or five days later, all the wounds were infected with hemolytic streptococcus. A leak of cerebrospinal fluid developed from one wound, and the patient died several weeks later from meningitis. A partial autopsy was obtained under difficult circumstances. There was an acute meningitis, but no abscess. It is not known whether the lateral sinus was thrombosed or not.

*Comment.*—The patient had no headache or vomiting. If she had been observed for a longer period, she almost certainly would have recovered without operative intervention.

The following case emphasizes the observation that choked disks in the presence of a focal infection, especially if there has been a thrombosis of the lateral sinus, does not necessarily signify the presence of an abscess of the brain.

*CASE 2.—Lateral sinus thrombosis. Choked disks. Recovery.*

A medical student, aged 19, was operated on for an acute condition of the right mastoid. The lateral sinus was accidentally opened and had to be packed. Convalescence was stormy for a few days, and then progress was satisfactory. Three weeks after the operation, a paralysis of the right sixth nerve developed. The disks were examined and found choked with an elevation of from 6 to 7 diopters, and with numerous patches of white exudate and flame-shaped hemorrhages. There was no headache or vomiting. Doctor Horrax of Boston saw the patient about this time and agreed that, despite the absence of headache, there was probably an inflammatory block producing an internal hydrocephalus. To determine whether this was true, the right lateral ventricle was punctured. Only a few cubic centimeters of fluid could be obtained, so the ventricles were not enlarged; furthermore, as far as one could determine through a small burr hole, the intracranial pressure was not increased. The patient was discharged from the hospital feeling well a few weeks later. At the end of three months, the disks were perfectly flat and vision was normal in both eyes. Two years later, the patient finished his medical course and was feeling well.

*Comment.*—Just how a choked disk is produced in these patients is not clear. The cases are not uncommon, and one should be conservative when dealing with a syndrome of lateral sinus thrombosis and choked disks, unaccompanied by headache or other signs of intracranial pressure.

Patients showing a localized disturbance of the physiologic function of the brain in the presence of an infective focus make up a large proportion of the "brain abscess suspect" group.

*CASE 3.—Localized meningitis and cerebritis of the left temporal lobe.*

A boy, aged 14, was operated on for an acute condition of the left mastoid. Two days later, his temperature rose to 103 F.; he became restless and difficult to manage. During the next three days, he gradually developed a marked aphasia and definite weakness in the right arm. It was also thought that he had defect in the field of the right eye. There was never any choking of the disks. This condition remained unchanged for two weeks. Puncture was made through a clean field into the left temporal lobe with negative results. The patient gradually made a complete recovery, although it was months before all the symptoms of aphasia cleared up.

*CASE 4.—Cerebritis of the left temporal lobe.*

The patient, aged 45, had had a discharge from the left ear for some years. The history of the present illness commenced about Sept. 20, 1927, when he wrote an incoherent letter to a friend. Eight weeks later, while playing cards, he became so confused that he could not continue. The following morning, he had difficulty with his speech. An operation was performed on the mastoid—the bone was sclerotic and little pus was found; a small amount of normal dura was uncovered over the temporal lobe. When seen seven days after his operation, he was drowsy and it was difficult to get his attention. He was unable to name common objects and became confused when asked to carry out simple commands. It was thought that there was a defect in the field of the right eye, although cooperation was poor. There had been no headache or vomiting, and the disks were normal. Although operation was urged, delay was counselled. The patient gradually recovered and apparently was perfectly well three months later.

Patients are not infrequently seen complaining of severe localized pain following a mastoid or frontal sinus operation. Usually this symptom gradually subsides and further operative procedures are unnecessary. In the following case, however, operation might have saved the patient's life.

*CASE 5.—Mastoid disease, sinus thrombosis, persistent localized pain. Death from purulent meningitis.*

T. G. H., a girl, aged 21, developed a cold two months previous to her admission to the Ear, Nose and Throat Service; the cold was followed by a discharge from the right ear. The discharge ceased two days before admission to the hospital, and since then there had been severe pain and tenderness over the right mastoid. A simple operation was performed on the mastoid; no pus was found; the dura over the sinus was congested and partially covered with granulation tissue. Following the operation, progress was satisfactory for nine days when the patient began to complain of frequent right-sided headache localized in the temporo-occipital region. The results of a complete neurologic examination, eighteen days

after the operation, were negative. The temperature was normal and the patient looked well, but she complained of persistent right-sided headaches which came on at any time of the day and lasted for varying periods. During the next five weeks, the patient continued to complain of these headaches, and every few days she had an attack of vomiting. The temperature occasionally rose to 99 or 100 F. There were many days when the patient felt much better, but undoubtedly there was a gradual increase of headache and vomiting. Seven weeks after operation, the spinal fluid was turbid and contained 9,000 cells per cubic millimeter, 60 per cent polymorphonuclear leukocytes, 38 per cent lymphocytes and 2 per cent red cells; 8 cc. of fluid was removed and was not examined for organisms. Following the puncture, the patient became rapidly worse; she died three days later with all the signs and symptoms of acute meningitis.

At the necropsy, a purulent thrombosis of the right lateral sinus was found. In places, the thrombus was well organized. The base of the brain was covered

*Series of Eleven Verified Cases*

Name	Age	Primary Focus of Infection	Site of Abscess	Date of Operation	Result
Mr. F. C.	45	Left middle ear	Left temporal lobe	August, 1924	Well, at work
Miss F. K.	18	Left middle ear; abscess of right lung	Right rolandic arm area	May, 1925	Well, at work
Mr. S. C.	45	Left middle ear	Left temporal lobe	February, 1926	Well, at work
Mr. P. G. (Case 8)	42	Left frontal sinus	Left frontal lobe	April, 1926	Died
Miss I. B.	25	Left frontal sinus	Left frontal lobe	September, 1926	Well, at work
Miss B. O. (Case 9)	6	Compound fracture right rolandic area	Right rolandic arm area	September, 1926	Died
Mr. H. C. (Case 10)	42	Boil, prostatic abscess, lung abscess	Left posterior temporal	October, 1926	Died
Mr. R. S. (Case 7)	17	Right frontal sinus	(A) Right rolandic arm area (B) Right frontal lobe	February, 1927	Well, at school
Miss J. S.	14	Left middle ear	Left cerebellum	March, 1927	Well
Mr. C. B. (Case 11)	18	Left frontal sinus	Left rolandic arm area	March, 1928	Died
Major S. (Case 12)	45	? Boil	Right hemisphere of cerebellum	September, 1928	Died

with a purulent exudate from which a pure culture of *Staphylococcus aureus* was obtained. There was no abscess of the brain or localized collection of pus beneath or outside the dura.

*Comment.*—Drainage of the lateral sinus even as late as a week before the patient died would possibly have saved her life. At no time during the course of the illness were there the usual signs and symptoms of septic thrombosis of the lateral sinus. The late development of the purulent meningitis, some six weeks after persistent right-sided headache, is unusual. An earlier lumbar puncture with the removal of only about 2 cc. of fluid could have been done without danger to the patient, and at the same time a modified Queckenstedt test, as suggested by Ayer, would have aided materially in a correct diagnosis (compression of the jugular vein on the side of the thrombosis would not have shown a normal rise and fall of cerebrospinal fluid in the manometer).

Probably the removal of 8 cc. of fluid hastened the end by spreading the infection. It is unwise and unnecessary to remove more than 1 or 2 cc. of fluid when there is any suspicion of a localized meningitis.

Rupture into the cerebrospinal fluid system may occur, and the knowledge of this possible catastrophe often makes it difficult to delay operation. Little can be done for the patient who has not sufficient resistance to localize the infection. Early surgical drainage before good localization is obtained will only increase the encephalitis and almost certainly hasten a fatal termination. Rupture after good localization

Fig. 1.—Chronic abscess located by feeling with a blunt pointed brain needle through a small burr hole and nick in the dura.

is rare, so that the danger of postponing operation is slight compared to the danger of too early intervention.

#### TECHNIC

The sketches illustrate some of the underlying principles which are thought to be important when dealing with a supratentorial abscess, well localized and walled off by a capsule, and not adjacent to an infection of the middle ear or frontal sinus.

A chronic abscess may be located by feeling it with a blunt pointed brain needle (fig. 1), through a small burr hole and nick in the dura. When the wall is well formed, the abscess feels like a rubber ball. In two of my cases, the capsule was so poorly formed that it was not felt, and pus coming through the needle was the only indication of the pres-

ence of an abscess. In a case that was thought to be one of tumor, the pus was so thick that it would not flow, but enough remained in the eye of the needle for microscopic examination and establishing a diagnosis.

When localization is not quite accurate, the abscess may be located at an angle either by feeling it with the needle or by the appearance of pus. In such a situation, the needle is left in place, while another burr hole is made over the top of the abscess at *x* (fig. 2) so that a second needle locates the abscess when passed at right angles to the brain. Drainage is then established through this latter opening. An abscess is not likely to be cured unless it can be drained through an opening directly over the point where it is closest to the surface. If it is located

Fig 2—Locating the abscess at an angle when localization is not quite accurate. The needle is left in place, while another burr hole is made over the top of the abscess at *X*, so that a second needle locates the abscess when passed at right angles to the brain. Drainage is established through the latter opening.

at a greater depth than 1 or 2 cm. from the surface, an attempt should be made, by making other burr holes, to locate a point where it is closer to the surface. To evacuate an abscess and place a tube to the bottom of it through any great thickness of brain is extremely difficult.

The opening in the bone is enlarged to a diameter of 2 cm. (fig. 4). The brain is transected down to the abscess. The capsule is incised and two retractors maneuvered inside the capsule. As the pus is sucked out, the retractors are worked to the bottom of the cavity. In all my cases intracranial pressure was such that even after the abscess had been emptied, the brain remained snug against the dura so that there

Fig. 3—The opening in the bone is enlarged to a diameter of 2 cm. The brain is transected down to the abscess. The capsule is incised, and two retractors are maneuvered inside the capsule. As the pus is sucked out, the retractors are worked to the bottom of the cavity.

Fig. 4—A tube the size of one's little finger, or larger, without perforations in the side is placed to the bottom of the abscess, and the retractors are withdrawn. Intracranial pressure converts the cavity into a straight sinus about the tube. Controllable herniation also commences through the small dural opening.

was no need to take special precaution against soiling beyond the dural opening. On the other hand, Adson told me that in some of his cases the abscess was so large that when it was emptied the brain fell away from the dura. In such a case, he suggests having retractors bent in such a manner that they hook up the wall of the abscess and thus hold the brain from falling away until the abscess cavity can be filled with packing about the drainage tube. The packing is then gradually withdrawn during the next few days, as the adjacent collapsed ventricle fills and holds the brain against the dura.

A tube the size of one's little finger, or larger, without perforations in the side, is placed to the bottom of the abscess, and the retractors are withdrawn (fig. 4). Intracranial pressure converts the cavity into a straight sinus about the tube. Controllable herniation also commences through the small dural opening.

The dressing is important. The tube is not tied in place, for fear of intracranial pressure causing it to break through into the ventricle. Strips of bandage 3 inches (7.6 cm.) wide and 12 inches (30.48 cm.) long, which have been autoclaved in petrolatum and so thoroughly impregnated, are built up in such a manner that the tube can be pushed out 1 cm., before impinging against the soft absorbent dressing. The foundation of bandage treated with petrolatum clings to the head so that the dressing does not slip and displace the tube. When the dressing is changed, it does not adhere to the cerebral hernia. Needless to say, the dressing should be done by the operator, so that there is no divided responsibility about keeping the tube in place. When the cavity has been thoroughly sucked out in the first place, there will be practically no discharge and the dressing need be changed only every few days. As the tube is pushed out, it is shortened. In a few days, the track is so well established that the tube may be removed and replaced after gentle irrigation of the sinus with a solution of chlorinated soda.

When the abscess is first opened, pus escapes rapidly, and intracranial pressure may pocket off part of the cavity (fig. 5). If possible, the cavity is inspected so that all the pus can be sucked out and the tube accurately placed to the bottom of the abscess.

Oblique drainage is unsatisfactory. A new opening should have been made and drainage established at  $x$  (fig. 6). Intracranial pressure produces hernia of that part of the brain which does not directly overlie the abscess. The tube is not pushed out, and the hernia is likely to be uncontrollable.

In a number of my cases the requirements illustrated by these sketches have not been fulfilled. The following case (figs. 7 and 8), however, demonstrates how satisfactory progress may be when a well localized abscess close to the surface is drained with the tube at right angles to the brain and placed to the bottom of the abscess.

Fig. 5.—When the abscess is first opened, pus escapes rapidly, and intracranial pressure may pocket off part of the cavity. If possible, the cavity is inspected so that all the pus can be sucked out and the tube accurately placed to the bottom of the abscess.

Fig. 6.—Oblique drainage is unsatisfactory. A new opening should have been made and drainage established at X. Intracranial pressure produces hernia of that part of the brain which does not directly overlie the abscess. The tube is not pushed out, and the hernia is likely to be uncontrollable.

TEMPORAL, CEREBELLAR AND FRONTAL ABSCESS ASSOCIATED  
WITH ADJACENT INFECTION

Additional problems require discussion when an abscess is associated with infection of the ear or frontal sinus, although the principles just reviewed remain applicable.

*Abscess of the Temporal Lobe Adjacent to Infection of the Middle Ear.*—If the patient is in coma when first seen, there is urgent need for drainage of the abscess, and if there is an infection of the ear on both sides it may be impossible to determine on which side the abscess is present. In such a situation, an exploratory puncture is made through

Fig. 7 (F. K. in table).—Five days after operation.

a clean field, just above the mastoid area, and if no abscess is located the same procedure is carried out on the other side. When the abscess is located, the burr hole is enlarged downward into the mastoid cells which are rapidly opened up. Drainage of the abscess is then carried out through this field, because at this point the abscess will be closest to the surface. Sufficient dura must be uncovered to permit proper opening and drainage as previously illustrated. A tube pushed in blindly may never get inside the abscess cavity.

If the patient is not critically ill when first seen, a thorough operation is done on the mastoid, and one is often agreeably surprised to find all intracranial signs and symptoms clear up. At this operation, a sinus

leading through the dura to a subdural collection of pus or to an abscess of the brain may be located. If so, the outlook is excellent as it is comparatively simple to establish efficient drainage by enlarging this sinus. (Just recently a case was seen at Dr. Frazier's clinic. Pus had been discharged from a sinus through the dura in the mastoid area. A soft catheter was passed into the sinus for 4 or 5 inches [10.16 or 12.7 cm.]. A small amount of potassium iodide solution was gently injected and x-ray examination revealed a subdural abscess on top of the hemisphere near the midline. An opening was made directly down on this abscess, and the patient was cured.) If no sinus is found, further intracranial

Fig. 8 (F. K., in table).—Four weeks after operation, showing all that was left of the 2 inch (5 cm.) straight sinus. A few weeks later, the hernia had receded, and the defect in the bone was filled with a dense scar. There was no residual weakness in the arm.

exploration is not carried out through this septic field. The patient is watched carefully, and if it is finally determined that intracranial exploration is necessary it is carried out in one of two ways:

1. If the diagnosis is practically certain, exploration is carried out by enlarging the mastoid wound and uncovering sufficient dura to work through.

2. If the diagnosis is not quite definite, an exploratory puncture is first made through a clean field above the mastoid area; if an abscess is

located, the burr hole is enlarged downward and drainage carried out through the mastoid wound. If no abscess is located, an exploratory puncture through a clean field does little harm, whereas exploration through septic dura in the mastoid wound might easily produce serious trouble.

In my two cases of abscess of the temporal lobe adjacent to infection of the middle ear, drainage was finally established through the mastoid area after sufficient dura was uncovered to permit proper exploration. In one case, the diagnosis was definitely confirmed first by an exploratory puncture through a clean field.

*Abscess of the Frontal Lobe Associated with Infection of the Frontal Sinus.*—The diagnosis is often in doubt in these cases, not only as to the presence of an abscess but as to the side on which it is located. The abscess may be adjacent to the frontal sinus or may be separated from it by several centimeters of brain. If an x-ray picture shows an osteomyelitis of the posterior wall of the sinus, and if there is no suspicion of involvement of the rolandic areas, the abscess is most likely adjacent to the sinus.

As a preliminary procedure, an exploratory puncture is made lateral to and above the sinus, to definitely locate the abscess. By palpating the abscess with the needle, one can usually determine whether it is adjacent to the sinus and should be drained through that area, or whether it is farther back and should be drained at some other point where it is close to the cortex. The exploratory incision is then closed tightly.

In a couple of days, after this incision has sealed off, the frontal sinus is opened for two reasons:

(a) At the exploratory puncture, it may have been definitely established that the abscess was adjacent to the posterior wall of the sinus and should be drained through the sinus.

(b) It has been decided that the abscess is not likely to be adjacent to the sinus, but one cannot be sure of this, and a sinus may be found through the dura, but the removal of loose pieces of bone, great care is taken not to tear the diseased dura by tugging on a bit of bone which may be attached to it. If a sinus is not found, the abscess is drained a few days later, either by opening the first incision and enlarging the bone opening or by making a fresh opening over a point where the abscess is thought to be closer to the surface.

The foregoing procedures are applicable only when the patient is not seriously ill. If the patient is in coma, drainage or tapping must be carried out immediately, preferably through an opening clear of the frontal sinus.

*Cerebellar Abscess Associated with Infection of the Ears.*—Something the same attitude is adopted as when dealing with an abscess of the temporal lobe. Search should be carefully made for an opening in the dura by laying the mastoid area well open and by reflecting the dura

from the outer part of the posterior surface of the petrous portion of the temporal bone. If no opening is found through the dura, intradural exploration is delayed, unless the case is urgent, or unless diagnosis is certain. If intradural exploration is, or becomes, necessary, the uncovered dura is cauterized in front of the lateral sinus, and an exploring needle is passed through this area. If an abscess is located at some distance from the surface, one might be content with tapping alone (this procedure will be discussed later under a separate heading). If the abscess is close to the surface and especially if the lateral sinus is thrombosed, an attempt is made to carry out tube drainage through the

Fig. 9.—Suggested site for drainage of a cerebellar abscess associated with disease of the ear. The dura is well exposed in front of the sinus. Additional bone is removed as indicated by the dotted line.

mastoid area. In my case, in which the patient recovered, this was done and the procedure was comparatively easy, as the lateral sinus was thrombosed and consequently was not in the way. Eagleton's suggestion that the sinus be obliterated is valuable. Usually, there will not be room to carry out tube drainage properly in front of the sinus, and in some manner the sinus must be obliterated so that the dural opening can be carried back through it. Crossing a nonthrombosed sinus may be made comparatively easy by collapsing the sinus above and below by gauze wedged in between the bone and dura. Figures 9 and 10 illustrate the suggested site for drainage in most cases.

It is here that the abscess is most likely to be close to the surface. Attempted drainage farther back behind the sinus through considerable thickness of cerebellum is courting disaster. It is technically difficult to get a tube properly placed in the cavity. Trauma and infection set up a severe encephalitis, and herniation is likely to become uncontrollable. Again one emphasizes the importance of draining at that point where the abscess is closest to the surface and of placing the tube to the bottom of the cavity after all the contents have been sucked out. The procedure of blindly pushing a tube in after pus commences to ooze

Fig. 10.—The dotted line illustrates the site of the incision through the dura across a thrombosed sinus or, if necessary, an artificially obliterated one, for drainage of a cerebellar abscess associated with disease of the ear.

out is often doomed to failure as the tube never enters the cavity, but slides along the outer wall of the abscess.

#### SIMPLE PUNCTURE AND DRAINAGE FOLLOWED BY IMMEDIATE CLOSURE OF THE WOUND

Simple puncture and drainage followed by immediate closure of the wound was advocated by Dandy in the October 30 number of *The Journal of the American Medical Association*, 1926. I have not had any personal experience with this procedure, but feel that in the future certain situations will arise in which it will be useful. In commenting on the

five deaths in this series, reference will be made to its possibilities. One's reaction at present is somewhat as follows:

If it is possible to place a tube to the bottom of a well encapsulated abscess, as shown in figure 2, recovery is likely to take place, and one is loath to discard such a procedure. If, however, at the time of initial exploration through a nick in the dura, pus is located at some depth, say over 2 cm., or if it is felt that there is a poor capsule, simple tapping would be resorted to, not so much, perhaps, with the idea of obtaining a permanent cure as to tide the patient over. Subsequent exploration, if necessary—and it appears that it would be necessary in the large percentage of cases—might locate the abscess in a site where it was closer to the surface and where tube drainage could be carried out through a

Fig. 11.—Two small chronic abscesses buried in a mass of reactionary tissue.

small opening without excessive damage to the brain and the fear of uncontrollable herniation.

#### COMPLETE REMOVAL OF ABSCESS

A small abscess may give rise to such a mass of reactionary tissue that it has to be treated as a tumor of the brain and be removed in toto. The following case (fig. 1) illustrates this point and also suggests that some of the patients who are cured following drainage or tapping may have a return of symptoms from a residue of infection causing sufficient reaction to bring about a tumor-like mass.

CASE 6 (fig. 11).—A woman, aged 45, was admitted to the hospital in coma. There were no relatives, and the only history obtainable was that she had complained of headache for some months and had been unsteady on her feet at times. Both disks were badly choked. No localizing signs could be made out. While

preparations were being made for puncture of the ventricles, the patient died. At necropsy a tumor mass the size of a large walnut was found buried deep in the right frontal lobe. On section, two small abscesses each about 2 cm. in diameter were found side by side in the mass. A marked edema of the right hemisphere had produced sufficient intracranial pressure to cause death. A pure culture of *Staphylococcus aureus* was grown from the pus.

*Comment.*—Cure in such a case by drainage or tapping could not be imagined. Death was brought about by an acute edema of the brain similar to that occasionally seen with comparatively small supratentorial tumors. A simple decompression alone might have been of value if the patient had been seen earlier; the ideal treatment, of course, would have been complete removal of the tumor-like mass.

#### COMPLETE HERNIATION OF ABSCESS

The following case which presents some unusual and interesting features will be reviewed before the analysis of the five deaths in the series. The opportunity is not likely to arise often in which pus may be drained from two sites inside the cranium at the same time. The final result has been most gratifying, despite the loss of considerable brain tissue.

CASE 7 (table).—*Three operations for two separate collections of pus. Recovery.* R. S., a boy, aged 17, was admitted to the hospital on Feb. 9, 1927, in a semistupor, following a generalized convulsion. He had been in good health until ten days previously, when he became aware of a pain over his right eye. He continued to play hockey, but was kept awake at night by the pain. In three or four days, a swelling appeared over the right frontal region; this was opened by an incision through the skin. Considerable pus escaped, and the pain was relieved. The patient, however, remained in bed, and was dull and apathetic, but nothing definite was noticed until the day of admittance to the hospital a few hours, he had a generalized epileptic seizure. After the patient had been in the hospital a few hours, he brightened up considerably, and a neurologic examination was carried out with good cooperation and with completely negative results. The incision in the skin over the right forehead was healed, and no swelling or tenderness could be detected in this region.

During the next six days, a series of epileptic seizures occurred, some of which were definitely localized in the left arm. The disks became acutely choked, although there was no vomiting or complaint of headache—the grip in the left hand became persistently weak. X-ray examination showed a cloudy right frontal sinus. Operation was decided on, largely because it was becoming impossible to control the epileptic seizures which recurred with increasing severity. The history was so short that it was feared that operation might do more harm than good.

*Operation.*—A burr hole was made over the prerolandic arm area on the right side; the dura was nicked, and there was an immediate spurt of a small amount of thick, white pus. The dura was opened farther, and one could appreciate that the pus was welling up between the arachnoid and dura. A trough was then cut in the bone forward for 4 cm., and the dura was laid open. When the brain was pressed away, small amounts of pus would well up. The arachnoid was not inflamed, and the dura appeared normal. Not more than from 3 to 5 cc. of pus

were obtained. The tension of the brain had not been relieved. It was felt that the observations up to this point accounted for the epileptic seizures, but that there was something further causing the increased tension in the brain. Accordingly, an incision was made over the frontal sinus; most of the anterior wall was found to be a sequestrum which could be lifted out. There was a defect in the posterior wall 1 cm. in diameter. A small opening could be seen in the dura through which pus was oozing. The opening was enlarged—pus poured out and a tube was placed to the bottom of a chronic abscess about the size of a small hen's egg.

The patient was discharged, apparently cured, in forty days. At the time of operation, *Staphylococcus aureus* was cultured from: (1) the rolandic area, (2) the frontal sinus and (3) the abscess of the frontal lobe.

The patient returned to the hospital three months later. Ten days previously, he had commenced to have headaches and gradually became dull and apathetic. Both the previous operative fields were bulging and tense; the disks were again choked. A puncture was first made through the operative field in the rolandic area with negative results. The old wound in the frontal region was opened. More bone was removed, and preparation was made to evacuate thoroughly an abscess in this site. Pus was located at a depth of 2 cm.; only a few drops were allowed to escape; the needle was withdrawn, as it was thought that a large abscess would be located without difficulty. Then commenced a harrowing experience. A 2 cm. incision was made in the scarred dura; the brain was transected, but no abscess was discovered, nor could the pus again be located with the needle. Considerable trauma to the frontal lobe resulted; the brain commenced to herniate; a small tube was left in, but the situation seemed hopeless. For the following ten days, the dressings were carefully done; on several occasions, herniated edematous brain which was overflowing the dural opening was cauterized off. Finally, one morning, the dressing was saturated with blood and some pus; there was a soft fresh cerebral hernia the size of an egg. This was cauterized off, and in the center of it a ruptured abscess, 2 cm. in diameter, was found. From this time on, convalescence was rapid.

The patient returned two months ago after completing a successful year in school. The ragged pulsating scar in the frontal region (fig. 12) was resected, and the bone opening was repaired with a piece of a celluloid soap box.

NOTE.—The history of this case has been carefully retaken from the mother and the patient. For a year before his first admittance to the hospital, he was having trouble in school, especially with algebra, in which subject he was at the bottom of the class. At no time during the past year did he have any headache or nausea or even complain of pain in the region of the frontal sinus. Despite the loss of a considerable amount of the right frontal lobe from herniation, the patient has a pleasing disposition and stood fourth in his class at school this past year, making nearly 90 per cent in algebra.

#### AN ANALYSIS OF FIVE DEATHS FOLLOWING OPERATION FOR ABSCESS OF THE BRAIN

CASE 8 (table).—*Death on the operating table which might have been prevented.*

History.—P. G., a man, was admitted on March 24, 1926, five and one-half weeks after the extraction of a tooth from the left upper jaw. The pain in the socket was intense for several days following the extraction. A discharge then developed from the left nostril, and the pain was relieved; two weeks later, severe, left supra-orbital pain developed. On April 11, he was confused; the pulse rate

varied from 44 to 48; there was bilateral choking of the disks. On April 12, a Killian operation was performed on the left frontal sinus. The sinus was filled with foul, yellow pus; the mucous membrane was stripped off and the bone found intact. After this operation, the patient's condition improved slightly, but two days later he had a convulsion and did not regain consciousness. When seen several hours later, the patient was draped for operation and was having about five labored respirations a minute. After a hurried consultation, a burr hole was made over the left frontal lobe. A large abscess was located close to the surface. A tube was placed to the bottom of the abscess when the patient died

Fig. 12 (case 7, R. S. in table).—Illustrating the repair of a pulsating defect in the bone with a piece of celluloid; the photograph was taken ten days after operation; the result two months later was satisfactory.

*Autopsy.*—There is no record that a culture was made. The abscess was the size of a hen's egg, had a well defined capsule and was separated from the frontal sinus by 1 cm. of apparently normal brain tissue. There was no evidence of adjacent localized meningitis. The abscess had not ruptured into the ventricle.

*Comment.*—This patient's death was hastened, if not caused, by the mistake of permitting him to lie on his back with the tongue obstructing respirations. For the moment, more attention should have been paid to

the patient's breathing and less to getting into the abscess. The patient really died of asphyxia.

CASE 9 (table).—*Compound fracture. Uncontrollable herniation. Death.*

B. O., a woman, had received a compound fracture of the skull over the rolandic arm area. At the time of injury, all the loose fragments of bone were not removed. The wound was infected, and osteitis with an underlying abscess of the brain developed.

When the patient was seen, there was a hernia cerebri the size of a large walnut. A small amount of pus was located in this, but the tension was not relieved. The hernia became uncontrollable, hemiplegia became complete and the patient died. Permission for an autopsy could not be obtained.

*Comment.*—The case illustrates well the teaching that in a compound fracture of the skull all loose fragments of bone and débris which may harbor infection should be removed.

CASE 10 (table).—*Boils, prostatic abscess, abscess of the brain, pulmonary abscess. Death.*

*History.*—H. C., a man, aged 42, developed a series of boils and then a prostatic abscess which was drained. *Staphylococcus aureus* was cultured from the pus. One month later, there was a period of from three to four days when he had a severe headache and high fever. Progress then seemed to be fair, but always there was some slight temperature, and the patient was listless and did not get out of bed. One month later, he coughed up a lot of sputum and it was felt that he had emptied an abscess of the lung, although thorough clinical and x-ray examination at this time failed to locate any lesion in the chest. He again improved, but a few weeks later again complained of headache and difficulty with his vision. When the patient was seen, he talked readily and cooperated well. The disks were normal, and one's first impression was that the patient did not have an abscess of the brain. Further routine examination disclosed a right upper homonymous field defect; then, careful examination was made for any manifestations of aphasia, and the following facts were made out:

1. When asked the year and the month he could not remember, but when the correct answer was suggested he knew it was right.
2. Various common objects were readily named.
3. He quickly forgot my name, and had had great difficulty remembering proper names for some weeks.
4. Although much interested in the Dempsey-Tunney fight, he could not read the newspaper reports and understand them. When they were read to him, however, he understood perfectly.
5. Ordinarily, he was accurate with figures, but now he could not add simple sums, either with or without the help of pencil and paper. A diagnosis of a lesion of the left temporal lobe was made. The lesion was thought to be far back because of the difficulty with figures and the fact that common objects could be readily named.

There was no urgency about intracranial exploration. The case was carefully observed for the next three and one-half weeks. The left-sided headache became more severe and was associated with considerable pain over the distribution of the fifth nerve. It was thought that the corneal reflex was lessened on the left. Vomiting was frequent, but there was no choking of the disks.

Exploration was decided on, and, because of the apparent involvement of the fifth nerve, the first puncture was made into the anterior part of the temporal lobe; the ventricle was located, and clear fluid escaped in small amounts. The brain was against the dura, but not under undue pressure. Another burr hole was made farther back, and through this four negative punctures were made. During the next ten days, the patient's condition was unchanged. The temperature was occasionally over 99 F. The white blood cells numbered 12,000. The field defect remained the same. He was able to carry on a fair conversation, only occasionally having difficulty in getting a word. The inability to read and do simple sums in arithmetic persisted. The disks now commenced to show some choking. Another burr hole was made over the extreme posterior and lower part of the occipital region. An abscess was felt at a depth of 2 cm. with a resistant capsule. A tube was placed in the abscess, but with difficulty, because it was not close to the surface and it was difficult to get retractors inside the capsule. In the four months following, moderate herniation with slight discharge persisted; the aphasia was little changed; the disks remained moderately choked. A pulmonary abscess was located, drained and apparently healed. Finally, the patient collapsed suddenly, quickly became unconscious and died in a few hours with a high temperature and fast pulse rate.

*Autopsy.*—An abscess in the lung, a large abscess in each kidney, one at the base of the bladder and also a right-sided empyema were revealed—all due to an infection with *Staphylococcus aureus*.

Figures 13, 14, 15 and 16 show the lesions in the brain.

*Comment.*—This is the one patient in the series whom one has no ambition to treat again. The pulmonary abscess and prostatic abscess had apparently been efficiently drained and healed months before death, yet large collections of pus were found at these sites at autopsy. The abscesses in the kidneys had not been suspected. During all this long illness (six months), the patient's general condition was fair; the temperature rarely rose above 100 F.; the white blood cells numbered around 12,000. Until there are some means of increasing the patient's resistance in this type of case, it is unlikely that many recoveries will be brought about.

CASE 11 (table).—*Abscess of the frontal lobe associated with disease of the frontal sinus. Death.*

*History.*—C. B., a youth, aged 20, was admitted on Feb. 19, 1928, three weeks after he had had an acute condition of the left frontal sinus and antrum. These were drained, and the patient was discharged from the hospital. The day before entrance, the mother telephoned to say that her son's brain did not seem to be functioning properly.

When he was first seen, no positive evidence could be made out, apart from some dulness and a feeling that his judgment and general mentality were not quite normal. It was suggested that a radical operation be performed on the frontal sinus. The sinus was filled with pus; there was no osteomyelitis of the posterior wall. Four days later, a generalized convulsion occurred. When he was seen shortly after this, there was a marked Babinski reflex, with a tendency to ankle clonus on the right side. No difference could be made out between the right and left arms.

During the next ten days, choked disks, a weakness of the right arm, a diminished right abdominal reflex and definite weakness of the right leg developed. Occasionally, there was difficulty in getting the right word, and the patient became dull and listless, and looked ill. A diagnosis of abscess of the brain could definitely be made. Three days later (four weeks after the first sign of intracranial trouble), an emergency operation had to be done, as the patient had gone into a state of deep coma.

Fig 13 (case 10, H. C. in table)—At the first operation, negative punctures were made at *N 1* and *N 2*. The puncture at *N 2* was higher than the operator planned for. If it had been placed lower, one of the undrained abscesses would have been located. Figures 14, 15 and 16 were made at the points designated as *C*, *D* and *E*. The site of drainage was at *O*.

*Operation*—A burr hole was made over the left prerolandic arm area. An abscess could be palpated at a depth of 3 cm anteriorly and toward the midline. The burr hole was enlarged in this direction, and the dura slit up. An area

appeared where the arachnoid and dura were glued together. At this point, the abscess could be palpated 1 cm. below the surface. The abscess was opened, and thin pus flowed freely; retractors were put into the abscess, but the wall was poorly defined and intracranial pressure was such that inspection of the cavity was difficult. The cavity was deep so that a tube 2 inches (5 cm.) long was placed in it. It was felt at the time that the abscess must be close to the ventricle. A short chain streptococcus was cultured from the pus. Shortly after the termination of

Fig. 14 (case 10, H. C. in table).—Section at *E* through the site of drainage. The posterior end of a fairly large abscess was being imperfectly drained. A smaller undrained abscess is seen at *A*.

the operation, the patient was conscious but, much to my dismay, cerebrospinal fluid was coming from the tube. The patient died a week later from meningitis and terrific uncontrollable herniation.

*Autopsy.*—The autopsy was carried out under difficulties, and the brain had to be removed through a relatively small opening in the bone. The ventricles and

surface of the brain were acutely inflamed. Loss of brain tissue from herniation had been so extensive that the original site of the abscess was a large ragged cavity opening into the lateral ventricle. The abscess wall could be seen (fig. 17).

CASE 12 (table).—*Cerebellar abscess unexpectedly found during an operation for a supposed tumor. Drainage of cisterna magna for five weeks. Death.*

Major S., aged 45, had had intermittent severe bouts of generalized headache for one and one-half years. The last attack persisted for several days, was uncon-

Fig. 15 (case 10, H. C. in table).—Section at *D*. The abscess *X* is the one that was being imperfectly drained. The posterior end of a large undrained abscess is just coming into view lateral and anterior to the one that was drained.

trolled by morphia and was associated with some vomiting. Good cooperation was obtained on examination. There was a moderate choking of both disks, and a diminution of the left abdominal reflex. On repeated examinations, no other positive signs could be elicited. No caloric tests were done. A ventriculogram showed

large lateral ventricles and a persistent filling defect in the right occipital horn. No defect could be made out in the eye field in this situation. A right occipital exploration was carried out with negative results. A large temporal decompression was left. The decompression remained soft for four days, and the headache was relieved. Headache and vomiting then became marked. The decompression bulged and was very tight. Dr. Percival Bailey saw the patient at this time and suggested that the lesion was probably in the posterior part of the

Fig. 16 (case 10, H. C. in table).—Section at C. A large abscess which was not located. It lies lateral and anterior to the one which was drained posteriorly. Two other small abscesses can be seen medial to the large one. The track of the negative exploratory punctures can be seen just above the abscess.

third ventricle, especially in view of the fact that the third ventricle was not clearly seen in the anteroposterior plate. Further ventriculogram studies were made. The third ventricle filled well. Lateral plates were not made for a study of the occipital horn in this series.

The usual Cushing cerebellar exposure was carried out. The midline was pushed to the left, and there was a marked herniation of the lower pole of the right hemisphere which could just be teased up from under the arch of the atlas. Puncture into the right hemisphere high up in the field met resistance at a depth of 2 cm. At first it was thought that the tentorium was the cause of the resistance. Several punctures were made and in the last one, which did not meet the usual resistance, thick pus was seen in the eye of the needle. No organisms could be

Fig. 17 (case 11, C. B. in table).—Shows the ragged cavity at the original site of the abscess. The right cerebral hemisphere weighed 665 Gm., whereas the left weighed only 545 Gm. This loss of brain tissue from uncontrollable herniation took place through a dural opening 3 by 2 cm.

seen in the microscopic examination. It was felt that the abscess was small and that perhaps it could be removed in toto. In view of the length of the history (one and a half years), it was hoped that the pus might be sterile. The cortex was transected down to the capsule which was firm and well defined. After getting

about half way around the abscess, thick, white pus began to ooze from the small opening in the capsule which had been made by one of the needle punctures. The deep part of the capsule was still firmly anchored in the site of the superior peduncle. The abscess was then freely incised; about 3 cc. of thick, white pus were sucked up and a tube placed to the bottom of the small cavity which was not more than 2 cm. in diameter. The abscess wall was about 3 mm. in thickness. The tube was brought out through a stab wound in the muscle and scalp flap. During these procedures, all possible precautions were taken again general soiling of the whole operative field. The usual closure was made with fine interrupted silk. A pure culture of *Staphylococcus aureus* was grown from the pus.

During the next week, progress was satisfactory. The patient was nursed with the wound exposed at all times, so that the slight discharge from the tube could be kept wiped away and not soil the incision in the scalp. The incision all healed firmly, but about the seventh day the patient's condition was not satisfactory. The supratentorial decompression was again becoming tight, and the upper part of the midline cerebellar incision was commencing to bulge. A few days later, the upper part of the midline incision was opened, and about 10 cc. of pus escaped from between the muscle and the scalp flap. Four days later, the supratentorial decompression became tight, and the temperature which had never been above 99.5 F., shot up to 104 F. The respirations became fast and labored, and in a few hours the patient was unconscious and death was imminent. The lower part of the midline incision was opened, the arches of the atlas and axis were removed and the dura was slit from above downward. Clear cerebrospinal fluid flowed freely. It was impossible to prevent contamination from the pus in the upper part of the incision, and it was assumed that a meningitis would develop, so a tube was tied to the dura with catgut.

Immediately, there was an improvement in the patient's condition, and a few hours later he was again conscious. Cerebrospinal fluid continued to flow freely. The supratentorial decompression collapsed, and the pulse rate and respirations became normal. Two days later, the cerebrospinal fluid was cloudy and *Staphylococcus aureus* was cultured from it, but there were no clinical signs of meningitis. The patient lived five weeks longer. Cerebrospinal fluid drained freely all the time. Gradually, the patient refused nourishment and sank into a semiconscious state; nasal feedings were given every three hours during the last ten days of life. Several days before death, the upper part of the midline incision was opened freely and a large collection of pus drained from beneath the muscle flap on the right side; for a short time it was hoped that this might turn the tide. Finally, the patient died from a failing heart, but without signs of respiratory failure. The supratentorial decompression remained soft to the end.

*Autopsy.*—Permission for a partial necropsy was obtained. The sinus from which cerebrospinal fluid had flowed continuously for five weeks before death was injected with methylene blue. The skull cap was removed and showed the sub-arachnoid space over both hemispheres filled with methylene blue (methylthionine chloride, U. S. P.), and without evidence of meningitis. The cerebellum was soft and was removed with great difficulty. The remains of the small abscess could be seen. There were large collections of pus in each angle. There was no gross spread of infection through the cerebellum itself. Section of the cerebral hemispheres showed a congenital occlusion of the right occipital horn which accounted for the filling of the defect with air and the consequent negative exploration in this area.

*Comment.*—After the abscess had been located, the history was reviewed. Two years before, the patient had several boils on the back of his neck on the left side. Six months later, he had the first bout of headache. In between bouts of headache, the patient was perfectly well, and never had any unsteadiness. An intermittent edema and herniation of the right cerebellar hemisphere was the probable explanation of the bouts of headache.

How much better for the patient if the operator had not located the lesion at the second operation, as a cerebellar decompression alone would have relieved the block in the circulation of the cerebrospinal fluid, and probably the abscess would have remained quiescent for years.

When the diagnosis was definitely established by the observation of pus in the eye of the needle, one should have stopped and been content with the decompression, or possibly some of the pus might have been aspirated. The few organisms along the track of the needle would likely have been taken care of. It is probably wrong to work on the assumption that any abscess is sterile. Certainly this patient's death was brought about by a contamination of the whole operative field and illustrates well how a deep abscess of the cerebellum should not be handled when unexpectedly found with the whole of the cerebellar region exposed. It was of great interest to find that the injection of methylene blue showed that the cerebrospinal fluid pathways were not blocked, even after a mild infection in the cerebrospinal fluid, and the gross collections of pus between the arachnoid and dura in the angles. If the patient had recovered, apparently there would have been no difficulty in reestablishing the normal circulation of the cerebrospinal fluid by closure of the sinus.

#### SUMMARY

A presentation has been made of personal views, largely from the standpoint of treatment. The five deaths in the series have been reported in detail and critically commented on.

# ELASTIC TISSUE IN MENINGEAL FIBROBLASTOMAS SO-CALLED "DURAL ENDOTHELIOMAS" \*

WILLIAM P. VAN WAGENEN

It was my good fortune to find in Professor Spielmeyer's collection of tumors of the brain a benign meningeal tumor—meningeal fibroblastoma—or as it is more widely known, a "dural endothelioma" which seems to offer well nigh conclusive evidence of the ability of the type cell of this tumor to form elastic tissue. This is of interest since it adds still another bit of evidence, though indirect, of the potential fibroblastic nature of the cells of this tumor. Fibroglia fibrils, collagen fibrils and elastic fibers are the well known products of cells potentially fibroblastic. As Mallory has pointed out, elastic tissue may and often does grow out from the dura into these tumors where it is being invaded. It may likewise arise within the tumor from the stroma or the blood vessels. In this particularly favorable specimen the elastic tissue did not seem to arise from either of these sources. The attachment of the tumor was relatively slender and stalked, being about 1.5 cm. in diameter. Serial paraffin sections failed to show any increase of elastic tissue in the dura. In the stalk and the portion of the tumor nearest the dura there was none whatever. In other respects this part of the tumor was typical of a meningeal fibroblastoma. The dura was definitely though not extensively invaded.

The tumor discovered at autopsy was a small one, measuring 3 by 4 cm. in diameter. It was hard and reddish and was not attached to the arachnoid. From the gross specimen a diagnosis of a meningeal fibroblastoma seemed unmistakable. Fixation and preservation had been made in 10 per cent solution of formaldehyde for six years. The tissues were stained for fibroglia fibrils with Mallory's phosphotungstic acid hematin after washing for forty-eight hours, fixing thin slices in Zenker's fluid and mordanting for seventy-two hours in 3 per cent potassium bichromate. By this method fibroglia fibrils could be demonstrated beyond question here and there. Elastic tissue was also stained by this method a bluish black when the fibers were coarse and heavy. The finer fibers did not stain well or usually not at all. Bailey's ethyl violet-orange was also used for fibroglia. For tissues fixed in formaldehyde it is difficult though possible to demonstrate good fibroglia fibrils here and there by this method. Elastic tissue stains a dark blue. The constancy of this stain is not so great as the better known Weigert's or Verhoeff's stain for elastic tissue. Foot's stain

for reticulum was used after refixation in Zenker's fluid and mordanting in 3 per cent potassium bichromate. Perdrau's stain and Mallory's aniline blue were used for connective tissue of the stroma. All of the material was embedded in paraffin and sectioned 6 microns thick. Well away from the dural attachment of the tumor—1 cm. or more—elastic tissue fibers were everywhere abundant (figs. 1 and 2). They were

Fig. 1.—Section of Meningeal fibroblastoma showing elastic tissue diffusely scattered through tumor tissue. Weigert's iron- resorcin-fuchsin stain; 6 microns  $\times$  120.

found between the typical large, flattened, spindle-shaped tumor cells where the stroma was scanty or well nigh absent as well as where it was more abundant. There was a good deal of variation in their size and shape and in the intensity of their staining reactions indicating an immaturity of many of the fibrils (fig. 3). As stated before, delicate fibroglia fibrils were to be found surrounding the cells in many areas.

In a few places with Bailey's ethyl violet-orange G. stain, which stains both fibroglia fibrils and elastic tissue, the former could be seen undergoing condensation to form elastic fibers (fig. 4). Hortega, according to Penfield, believes that this is not an uncommon means by which elastic tissue may be formed. Psammoma bodies were fairly numerous indi-

Fig. 2.—Elastic tissue from same section as in figure 1. Weigert's iron-resorcin-fuchsin stain; 6 microns  $\times$  860.

cating a slow growth of the tumor. Mitoses were not observed. Whorl formation was fairly common. The connective tissue stroma was extremely scanty, particularly where the elastic tissue was most dense, and it seems unwarranted to think that it had given rise to such an abundance of elastic tissue as existed.

Mallory<sup>1</sup> has likewise observed elastic tissue in these tumors but believed that it is an ingrowth from the dura. He has also pointed out the fibroblastic nature of these tumors and showed that they are not derived from the "dural endothelium," which does not exist. For the so-called dural endothelioma he has proposed the name of arachnoidal fibroblastomas. Penfield,<sup>2</sup> in an excellent study of the benign tumors

2. Penfield, Wilder: The Encapsulated Tumors of the Nervous System—Meningeal Fibroblastomata, Perineural Fibroblastomata and Neurofibromata of von Recklinghausen, *Surg. Gynec. Obst.* **45**:178, 1927.

Fig 4—Early formation of elastic fibrils from condensation about long delicate fibroglia fibrils Water color drawing Bailey's ethyl violet-orange G stain,  $6\text{ u} \times 1,200$

of the central nervous system, has shown the close relationship of these tumors to those of the eighth nerve and of the peripheral nerves known under the name of von Recklinghausen's disease. He has suggested the somewhat more comprehensive and inclusive term of meningeal fibroblastomas for them. Rhoads and I,<sup>3</sup> in extending this study with reference to the tumors of the eighth nerve, found abundant elastic tissue arising from the cells of the tumor where there could be no question of invasion from the dura. We also believed that the presence of elastic tissue in these tumors of the eighth nerve lends support to the conception of their potentially fibroblastic nature and would likewise designate them as meningeal fibroblastomas (of the nervus acusticus).

#### CONCLUSION

The type cell of the meningeal fibroblastoma—so-called "dural endothelioma"—can apparently give rise to elastic tissue. This is taken as another bit of evidence of the potentially fibroblastic nature of these tumors. A description of a tumor is presented in which elastic tissue was found in abundance well away from and unassociated with the dura. The elastic tissue was in too great abundance to come from the stroma. The variations in size, shape and staining reactions and its close relationship to the tumor cells strongly suggest its origin from the cells. Coalescence of and condensation about fibroglia fibrils to form elastic tissue were observed. The designation of the so-called "dural endothelioma" by Penfield as meningeal fibroblastomas seems to be a most comprehensive one.

# POST-TRAUMATIC HEADACHE TREATED BY SPINAL INSUFFLATION OF AIR \*

DOUGLAS BOYD

The speed of urban life accounts for an increasing number of cranial injuries, which may not necessarily prove fatal, but often result in distressing and disabling headaches and dizzy sensations. These symptoms have been difficult to relieve. Patients with such symptoms form a persistent group in the traumatic clinic of Dr. Forrester, Dr. Lyman and myself, and they continue to report until the supply of palliative measures is exhausted. Often these complaints may be stimulated or aggravated by the desire for compensation or by anticipation of a successful lawsuit. This feature should not, however, lead one to discount these symptoms, for we have observed the same prolonged discomfort in a number of independent, intelligent patients in whom desire for compensation (or revenge) played no part.

All these patients complain of similar persistent headache, sensations of dizziness, restlessness and, usually, increased fatigue. These symptoms may last for a few months to a year or more, but gradually decrease in severity until they finally disappear. It is the long duration of distress and disability that causes an important economic loss.

We have treated a large number of patients with cranial injuries in the accepted conservative ways, usually over a period of several months. Our results were not encouraging, for often after careful study such patients would be dismissed finally, still complaining of some headache. Our records showed entirely normal physical signs, but the headaches remained.

Encouraged by Penfield's<sup>1</sup> report of success in seven patients treated by lumbar insufflation of air, we began in January, 1928, to use this method. Ten patients have now been treated, with results here reported.

## TECHNIC

We have used the technic described by Penfield: "The puncture is carried out in the operating room [as a major procedure], with complete aseptic technic. The patient may be given  $\frac{1}{4}$  grain of morphine at the start and should receive more later if necessary, or scopolamine may be used with morphine (Straus and Friedman).

"If the location of the headache is rightsided, place him on his left side, on a horizontal table. [This position is most important in order to allow the injected air to pass to the upper portion of the subarachnoid space.] Do a lumbar puncture

---

\* From the Traumatic Clinic of Drs. Forrester, Lyman and Boyd, Chicago.

1. Penfield, W.: *Chronic Meningeal Headache and Its Specific Treatment by Lumbar Air Insufflation*, Surg. Gynec. Obst. **45**:747, 1927.

and measure the spinal fluid pressure. Then tip the table so that the head is approximately thirty to forty centimeters above the feet. If the headache is in the middle or anterior third of the head, rotate the brow up about forty-five degrees or less. In this position air passes directly to the fronto-parietal region via the basal cisterns, very little enters the ventricle. . . .

"Withdraw fluid in five cubic centimeter amounts, alternately injecting after each withdrawal five cubic centimeters of air which has been filtered through cotton."

We have found an accurately fitted Luer syringe much simpler in use than the three way system used by Penfield. The syringe is always available, easy to handle and much less expensive equipment than Penfield's. It has proved satisfactory in our hands. The air is, of course, drawn in through sterile cotton before injection.

"About one hundred cubic centimeters of air or less may be thus injected [depending on the amount of spinal fluid drained] and it will completely fill the cerebral arachnoid spaces and basal cisterns. At the close the pressure should be about normal.

"Without altering his position, the patient is sent to the x-ray room where horizontal and perpendicular plates are made in each head-position by the usual routine. . . . Before radiographing the head in each new position (i. e., occiput up, other side up and brow up), the head is oscillated thoroughly so that the air is carried through all parts of the subarachnoid space before the end of the procedure."

The patient should then remain flat in bed until the headache caused by insufflation has entirely disappeared (from two to eight days in our series). We have kept the patients with lateralized headaches placed in bed so that for the first several days the affected side was uppermost. This was in order that the air might remain in the part in which we desired it.

We have elevated the head of the bed on low shock blocks, as Penfield suggested. The air disappears slowly, for roentgenograms taken immediately, at twelve, twenty-four and one hundred hours on each of our patients, demonstrated considerable air to be present at all these intervals. Usually the headache disappears before complete disappearance of the air. In all cases studied, the roentgenograms showed no air in the cranium after twelve days.

The amount of cerebrospinal fluid removed varied from 50 cm. in our first patient, to 100 cm. in case 9. In all patients, after our first, we drained all the fluid we could obtain. The subsequent reactions and the final results obtained did not seem to bear any relation to the amount withdrawn.

#### REACTIONS

All patients began to complain immediately during the procedure of an increase in the severity of the headache. This headache was generalized, and much more severe than previously experienced. It usually reached a maximum in a few hours, then gradually subsided, to disappear entirely in from two to five days. In only one instance were symptoms of increased intracranial pressure observed. This patient had projectile vomiting several times during the hour immediately following insufflation. We attributed the pressure symptoms to an increased intracranial pressure due to a technical fault in replacing the fluid withdrawn. This was not repeated.

No patient developed fever, nor was any evidence of infection noted. During the insufflation, the pulse rate was noted to rise consistently from 10 to 20 beats per minute. The rise was never alarming and in every instance returned to normal within twenty-four hours. The blood pressure rose (insignificantly) during the procedure. The systolic pressure remained higher than the preoperative level. This seemed important, for in several patients observed to have a subnormal blood pressure and associated symptoms of lassitude and drowsiness before the insufflation, the rise in blood pressure was sufficient to bring this to normal. With this rise in blood pressure, the symptoms of drowsiness and easy fatigue disappeared.

Neither the reactions nor the symptoms following puncture seemed related to the amount of air replacing the cerebrospinal fluid removed. The postpuncture symptoms were seen to be equally severe in all. It is interesting that no significant change in the character and cell count of the spinal fluid could be found at the second puncture in case 1.

#### REPORT OF CASES

##### CASE 1.—*Headache and dizziness for a period of four weeks following trauma.*

Louis M., married, white, a Slavic laborer, aged 39, was under treatment and observation from the time of his injury; he suffered a contusion over the occipital region when he fell from a wagon onto the pavement. He was unconscious for about ten minutes, was taken to a hospital where he remained for a short time, and was then sent to his home. The results of the physical examination, aside from a contusion on the scalp, were entirely negative. He was treated at home for about three weeks by rest in bed, sedatives, dehydration with large and frequent doses of magnesium sulphate. His headaches were intermittent, were generalized over the skull, and seemed to be worse at night. No medication or maneuvers seemed to relieve these headaches, and after varying lengths of time they would pass away gradually. Roentgenograms were taken of the skull, but did not show any fracture. The blood pressure was 115 systolic, 80 diastolic; the Wassermann reaction of the blood was reported negative.

*Lumbar Insufflation.*—The spinal fluid was clear, with 6 cells per cubic millimeter; the Wassermann reaction was negative.

In the operating room with aseptic technic, 50 cc. of spinal fluid was removed in 5 cc. amounts and alternately replaced by 5 cc. amounts of air which had been filtered through cotton. During this procedure the pulse rate rose from 70 to 100; at the termination of the procedure the blood pressure was 132, systolic and 90, diastolic, showing a rise of 17 mm. of mercury in systolic pressure. Immediately the patient complained of severe generalized headache, much worse than he had experienced prior to the injection. He was taken directly to the x-ray room where a roentgenogram showed well outlined or defined brain convolutions; the general picture had a cottony appearance. A shadow was observed in the midportion of the superior vault that suggested the position of the falxcerebri in the portion of the air trap in that location.

The man had severe headaches for about three days; the headaches gradually decreased. He complained of feeling very weak, and his appetite was poor. The pulse rate returned to normal in twenty-four hours; he complained of some head-

ache in the posterior occipital region; previously, all the headaches had been generalized. He was kept in bed in the hospital for about ten days, and then discharged to his home. Four weeks after the injection, he reported that the headaches and dizziness had entirely disappeared. He complained of some weakness at that time. Physical and neurologic observations were normal, and he was discharged from further treatment. Seventeen days later he returned complaining of severe frontal headaches but a complete relief from dizziness, the headaches, according to his statement, suddenly appearing two months after the first injection. Lumbar insufflation was again done, using the same technic; this time 75 cc. of spinal fluid was removed, and a similar quantity of air was injected.

Following this second injection, he remained in the hospital about one week, and gained complete relief from headache.

Six weeks following the second injection, the man was entirely free from headaches and was discharged to return to work. We have heard from him on several occasions; he has continued to work and says that he has occasional mild headaches.

*CASE 2.—Headaches and dizziness of five weeks' duration following trauma.*

Joseph M., a southern Italian laborer, aged 52, was struck on the head by a falling timber. He was somewhat dazed but not unconscious. He was under our observation and treatment from the time of injury. He suffered a laceration of the right parietal region; otherwise the examination immediately after injury showed no fracture. The Wassermann reaction of the blood was negative.

A short time after the injury the patient developed muscular weakness in the left arm and left leg, with exaggerated reflexes in these extremities. He complained continually of frontal headaches from which he could obtain no relief. Six weeks after his injury, lumbar insufflation was done.

*Lumbar Insufflation.*—The spinal fluid was clear, with 4 cells per cubic millimeter; the Wassermann reaction was negative.

The patient was placed on his right side, and the lumbar puncture was done in this position. His head was elevated and rotated so that the frontal region was uppermost, and in this position 75 cc. of spinal fluid was removed in from 5 to 10 cc. amounts, and replaced alternately by equal amounts of air which had been filtered through cotton. The patient had immediate severe generalized headache and vomited in a projectile manner. He was taken directly to the x-ray room where roentgenograms showed a good diffusion of air throughout the frontal region. He was then placed in bed, kept on his back with the head of the bed on low shock blocks, keeping the frontal region elevated. He complained of severe frontal headaches for four or five days. He was discharged to his home from the hospital about two weeks after the insufflation. A month after the insufflation, he began to develop evidence of neurosis, complaining of complete loss of hearing and sight and severe pain in the lower part of the back at the site of the lumbar puncture.

Examination showed his hearing and vision to be almost normal; he recovered the strength and use of his limbs in a few months and never at any time showed any atrophy of these muscles. The patient was, according to his statement, unimproved by lumbar insufflation. After careful examination, observation and consultation with a neurologist, he was discharged, but complained of dizziness and constant headaches at the time of his discharge.

*CASE 3.—Left parietal headaches and dizziness two and a half months after trauma.*

Tony R., married, an Italian laborer, aged 38, was struck on the head and back by some falling timbers. He was dazed, but retained consciousness. For two months he was under our care, being treated by rest in bed, bromides and frequent large doses of magnesium sulphate in the weeks immediately after injury. The headache was continual, aggravated by exercise, and usually localized in the parietal region. The systolic blood pressure remained at 110 mm. of mercury; the patient was drowsy and sluggish in reaction. Roentgenograms of the skull showed no fracture. The Wassermann reaction of the blood was negative.

*Lumbar Insufflation.*—The spinal fluid was clear, with 6 cells per cubic millimeter; the Wassermann reaction was negative.

Spinal puncture was done with the patient on his right side, the head slightly elevated and maintained so that the left parietal region was uppermost. Approximately 77 cc. of spinal fluid was withdrawn in 5 cc. amounts, being alternately replaced by 5 cc. of filtered air. The patient complained immediately of severe generalized headache and a feeling of faintness. The pulse rate increased 10 beats per minute. Roentgenograms showed the characteristic cottony appearance of diffused air covering the anterior two thirds of the left cortical area.

Headache was severe for three days, then gradually subsided to disappear entirely in a week. The patient remained in bed during this time on his right side and back. Dizziness remained a persistent feature but came at less frequent intervals, namely, about three times during a week.

Three weeks after insufflation, he returned to work at his own request. This caused a return of headaches, mild in degree, which lasted several months. While not entirely relieved, he was so improved over his previous condition, we did not feel a second insufflation desirable or necessary.

*CASE 4.—Frontal headache and dizziness of three and a half months' duration.*

Charles S., married, a Norwegian carpenter, aged 51, was struck on the crown of the head by a hammer falling from above. The blow was glancing and caused only a minor wound of the scalp. He was not made unconscious, but seemed unusually upset so he was kept in the hospital about eight days. He spent seventeen days in bed, following which he was up and around. We first saw this patient one month after his injury when he complained of frontal headache, dizziness and marked fatigue. He grew introspective, developed multiple complaints, loss of smell, loss of vision and loss of taste. Examination, including a neurologic test of the special senses, resulted in consistently negative or normal observations. Roentgenograms of his skull did not show fracture. The Wassermann reaction of the blood was four plus at three examinations. He was given a course of anti-syphilitic treatment, but he continued to grow worse. In a final attempt to relieve the patient's disability and distress, we offered him lumbar insufflation.

*Lumbar Insufflation.*—The spinal fluid was clear and contained 117 mg. of sugar per hundred cubic centimeters; no cells were seen. The Wassermann and Noguchi reactions were negative.

Lumbar puncture was done with the usual technic, 75 cc. of spinal fluid being removed in 5 cc. amounts, and alternately replaced with equal amounts of filtered air. The patient complained immediately of severe generalized headache. Roentgenograms taken immediately showed the ventricles well filled and air diffused through the arachnoid spaces.

He was kept in bed in the hospital for ten days. The headache changed in character, becoming localized in the occipital region, but was equally distressing. He told us that the air continued to move around in his head, annoying him constantly, though no air could be demonstrated in the subarachnoid spaces by roentgenograms.

Depressed, anxious, introspective still, he went to bed again and remained there for two weeks. Dr. James C. Gill, neurologist, who saw him about two months after insufflation, found no objective neurologic symptoms and confirmed our diagnosis of "psychoneurosis."

He was finally discharged unimproved, and later obtained a cash settlement from an insurance company.

Insufflation, we feel, should not be considered a failure in this case. We frankly tried this procedure in the face of unfavorable signs, in order to learn what might be accomplished in relieving an obvious psychoneurotic individual.

CASE 5.—*Post-traumatic occipital headaches of four weeks' duration.*

Thomas B., married, a laborer, aged 39, four weeks before lumbar puncture was done, was injured when a brick fell about 29 feet and struck him on the head and shoulder. He was knocked unconscious for about five minutes. He was treated by a physician by rest in bed and sedatives. He came under our observation about three weeks after his injury, complaining of continual occipital headaches and "ringing" in both ears. Headaches occasionally radiated to the frontal region and seemed to be aggravated by any form of activity and made more severe particularly when he leaned over to tie his shoes or when he made a sudden turn in walking.

The results of the physical examination were negative, except for a healed laceration over the upper central occipital region. Roentgenograms of the skull, including stereoscopic lateral films, showed no fracture.

*Lumbar Insufflation.*—The spinal fluid was clear, with a pressure of 32 mm. of mercury, and 2 cells per cubic millimeter; the Wassermann reaction was negative.

The man was placed on his side, the head being rotated as far as possible with the occipital region uppermost. The head of the table was elevated. Lumbar puncture was done, 70 cc. of clear spinal fluid being withdrawn in 5 cc. amounts and replaced alternately by equal amounts of air. The patient immediately complained of severe generalized headache; the pulse rate increased about 12 beats per minute; but there was no other reaction. Pneumograms taken immediately showed that there was a moderate amount of air spread over the anterior half of the cortical surface and a large bubble of air in the anterior horn of the uppermost ventricle. Films taken twenty-four hours later showed no change, except a slight decrease in the air in the ventricle; films taken after one hundred hours showed considerable decrease in the amount of air, but it was still clearly visible over the same distribution. The man remained in the hospital for about one week. He suffered considerable headache for about twenty-four hours and then gradually began to improve; the headaches entirely disappeared in three days, and six days after the insufflation he was discharged. He said that he felt much better. He continued to improve and was discharged from treatment five and one half weeks after this injection with no headaches but with occasional transient short periods of dizziness. The physical and neurologic examination at that time was negative.

This patient was much pleased with the result achieved and felt very grateful for the relief from his suffering.

CASE 6.—*Left temporal headache seven months after head trauma.*

C. P., married, a carpenter, aged 41, was struck over the left side of his head and shoulder by a falling timber. He was unconscious immediately and for forty-six hours following. Treatment was given in a hospital where he remained in bed for one month. Following this he went home, gradually increasing his activities, but spent a large part of the time in bed. We first saw him about six and one half

months after his injury. He was unable to work and complained of left temporal headaches of irregular occurrence but usually worse at night. Dizziness was constantly present, and aggravated by sudden changes in position. Insomnia annoyed him nightly.

Examination at that time revealed a low blood pressure, 113 systolic, 80 diastolic and a dull, sleepy and listless facial expression. We noted he staggered somewhat on rising from a prone position. Otherwise normal observations were recorded. Roentgenograms of the skull were normal without evidence of increased intracranial pressure or fracture.

*Lumbar Insufflation.*—The spinal fluid was clear, with 3 cells per cubic millimeter; the Wassermann reaction was negative.

Lumbar puncture was done six and a half months after injury. The patient was placed on his right side with the head slightly rotated to bring the left temporal region uppermost. Seventy cubic centimeters of spinal fluid was withdrawn in 5 cc. amounts, similar amounts of filtered air being alternately injected. The pain after insufflation in this instance was not so severe as usually noted.

Roentgenograms taken immediately showed the air confined to the left subdural space in its anterior two thirds. Subsequent plates taken twenty-four and one hundred hours after the injection showed a gradual diminution of the air.

The man remained in bed in the hospital about ten days. His headache rapidly disappeared in a few days. He was bothered by a fatigue and generalized weakness for about three weeks. The nervousness and insomnia disappeared entirely almost immediately. The look of drowsiness and listlessness entirely disappeared; he felt much brighter, and told me he would gladly go through the treatment again, in spite of its attendant pain, to gain the great relief it gave him.

About nine weeks after lumbar air insufflation, he asked to be returned to work and was discharged. He has had no recurrence to date, four months after treatment.

*CASE 7.—Frontal headache and dizziness four months following trauma.*

F. J., single, a carpenter, aged 32, was struck on the occipital region by several planks falling from above. He was made immediately unconscious for a few moments. Treatment was rendered in a hospital for one month, where the roentgenograms were normal and physical examination revealed only a small hematoma over the superior occipital region. We first saw this patient about five weeks after his injury. At that time he complained of a constant severe frontal headache, occasional occipital headaches and dizziness. He seemed dull, drowsy and introspective. He could not work and was frankly worried about his condition. The tonsils were large, cryptic and appeared inflamed. Neurologic examination was objectively normal. The Wassermann reaction was negative.

*Lumbar Insufflation.*—The spinal fluid was clear, with a cell count of 6 per cubic millimeter; the Wassermann and Noguchi reactions were negative.

By lumbar puncture, 75 cc. of spinal fluid was removed in 5 cc. amounts, being alternately replaced by similar amounts of filtered air. The patient was placed on the table on his right side with the head rotated to bring the frontal region uppermost. The reaction was severe; the pain immediately following and for twenty-four hours after puncture was intense, requiring repeated medication for relief. He remained in bed in the hospital for ten days and was discharged in a cheerful bright mood, entirely free from headache. He remained so for over three weeks; then the tonsils again became inflamed. He was quite sick for about a week with fever, generalized muscle pains and malaise. During this period, the headaches returned. Later, the headache largely disappeared. The patient regarded this

discomfort as slight compared to his experience prior to the puncture and did not consider a second puncture necessary. About six weeks after treatment, he was discharged to return to work.

CASE 8.—*Dizziness and headache of six weeks' duration following trauma.*

R. W., a robust negro laborer, married, aged 29, received an injury to his head when the pan of a concrete mixer fell, striking him. He was unconscious for thirty-five minutes. We saw him soon after the injury, and found him dull, sleepy and slow in reaction. The results of the physical examination were otherwise normal. Roentgenograms of the skull disclosed no fracture. He complained continually of a constant headache, generalized and associated with dizziness. These symptoms remained unrelieved under treatment by rest in bed, dehydration with magnesium sulphate, and frequent large doses of bromides.

*Lumbar Insufflation.*—The spinal fluid was clear with increased pressure, coming in a jet from the needle. The specimen was lost.

With the usual technic described, 75 cc. of spinal fluid was removed in 5 cc. amounts, and replaced by similar amounts of filtered air. The head was rotated through the widest range possible to give a general distribution of air. Pneumograms could not be obtained.

The reaction in pain was unusually severe. The patient complained bitterly of headache for forty-eight hours; then it suddenly disappeared. He remained in bed in the hospital one week, then returned home entirely relieved from symptoms. Two weeks after puncture, he was bright and cheerful, with the normal carefree manner of his race. He requested to return to work and was discharged to do so. There has been no recurrence of symptoms in two months.

CASE 9.—*Left frontal headache of twenty-four days' duration.*

C. H., married, white, an American laborer, aged 40, was injured by the explosion of an air hammer, when a piece of steel flew off and struck him on the left side of the forehead, knocking him unconscious a few moments. We saw the man immediately after injury and treated him. Examination revealed only a small irregular laceration on the scalp of the left side of the forehead. Roentgenograms of the skull were normal. The patient thought that the injury was so trivial that he refused to stay in the hospital even over night. Headaches, well localized in the left frontal region, continued to trouble and disable him. They grew steadily worse. The blood pressure prior to puncture was 110 mm. systolic and 70 diastolic.

*Lumbar Insufflation.*—The spinal fluid was clear, with 8 cells per cubic millimeter; the Wassermann reaction was negative.

Lumbar puncture was done with the patient on his right side with the left frontal region uppermost. One hundred cubic centimeters of spinal fluid was withdrawn in 5 cc. amounts and replaced by similar amounts of filtered air. The spinal fluid pressure was 30 mm. of mercury. He had a severe immediate reaction, rapid pulse rate and an intense generalized headache. He complained of a great sense of weakness and faintness. Pneumograms taken immediately showed the air distributed over the entire frontal half of the subarachnoid space. There was a small amount in the anterior horn of the ventricle. By the time the patient returned to bed, the pulse rate was slower, the headache less severe, and he felt much stronger.

The headache rapidly decreased, to disappear entirely after three days. The patient remained in bed five days, was then discharged from the hospital, the only complaint being some weakness in the muscles of his legs. At this time, the blood pressure was up to 120 systolic.

About three weeks after treatment he had no headache, no dizziness, and felt well in every way. He was much pleased with this improvement, and said that he regretted feeling so good because he knew he could get no money from the insurance company!

CASE 10.—*Frontal headache and dizziness of twenty days' duration.*

Mark S., single, a Hungarian laborer, aged 45, was struck on the crown of the head by a small object falling from above. He was dazed, but not made unconscious. There was a small laceration of the scalp. Roentgenograms were negative. The headaches grew progressively worse, and in an effort to check this, lumbar insufflation was done about twenty days after his injury.

The insufflation was done with the usual technic. We removed 60 cc. of spinal fluid, replacing this by an equal amount of filtered air in 5 cc. amounts. Following this, the headache seemed to change little, for even after one month he was disabled and continued to complain.

In our opinion, this patient had insufflation too soon after the trauma, before conservative measures had been completely tried and before his condition had reached a stationary point of recovery.

#### RESULTS

Three of this group of ten cases must be considered failures. In case 2, there was definite evidence soon after injury of cortical damage in the right motor hemisphere. Muscular weakness was noted in the left arm and leg, with increased reflexes in these extremities. The patient, an elderly Slavic laborer who spoke no English, was immediately and continually impressed by the severity of his injury and by fear fostered by his family. Later he developed a traumatic neurosis, complaining of loss of vision and hearing, both of which were shown to be normal by examination. In our experience with many injured workingmen, the patient in case 2 is a type we never see recover subjectively from an injury to the head.

It is possible as well that in such an injury the cerebral damage was severe enough to cause permanent mental change. We feel, in retrospect, that in this instance it is too much to expect entire relief from any single therapeutic procedure.

In case 4, the second failure, the patient gained no relief from lumbar air insufflation. He presented features in common with the patient in case 2, namely, he was overwhelmingly impressed by his really trivial injury. He developed early signs of a neurosis, complained of complete loss of taste, smell and vision. Examination in consultation proved these complaints groundless. His vision was 20/20 with glasses; he named odors and taste of common dilute substances. He grew very introspective. This man's Wassermann reaction of the blood was strongly positive on three separate examinations, though we found the Wassermann reaction of the spinal fluid negative, and no evidence of syphilis of the central nervous system could be demonstrated. He

was examined by Dr. James C. Gill, neurologist, who diagnosed "psycho-neurosis." The patient's symptoms were relieved by a cash settlement for his injury.

#### SELECTION OF CASES FOR TREATMENT

Considering the patients described as failures, and by comparing them with those who were successfully treated, we feel that this therapy should properly be confined to a selected group of sufferers from post-traumatic headache. Those patients who show definite cerebral damage we believe should not be so treated, or perhaps may be treated after all objective evidence of a cerebral pathologic process has disappeared. We further believe that little benefit, in fact, harm, may be done by this procedure in those patients who show a developing neurosis or psycho-neurosis. A study of this group of patients as compared with patients with similar injuries who were treated by more conservative methods suggests that insufflation should not be done until conservative treatment has been carried out for from a month to six weeks. Some of our patients who were relieved were treated by insufflation earlier with good results, but we shall, in the future, postpone insufflation until a thorough trial of more conservative methods has been completed.

Our group of patients has been treated sooner after the injury than the group described by Penfield. We have similar results, but feel the treatment will be less often needed or necessary and more successfully used late, rather than early, following the trauma. Case 10 well illustrates this fact. This patient was treated by insufflation about three weeks following injury in an attempt to relieve a headache of increasing severity. Some improvement was admitted, but the result has not to date been definitive.

#### PATHOLOGY

It seems likely, as Penfield suggested, that these head symptoms following trauma are caused by a common mechanism. Our conception of this mechanism remains unclarified by any definite evidence furnished by pathologic or physiologic studies.

The clinical evidence suggests to us that the cause lies in a disturbed circulation in the cerebrospinal fluid. Patients treated by repeated lumbar puncture immediately following head trauma are not so badly troubled by headache and dizziness later. Active early dehydration treatment by magnesium sulphate intravenously or by bowel is equally helpful in avoiding some late symptoms. It is our feeling that the cause of the headaches is more often increased intracranial pressure than local irritation. We have repeatedly observed little or no headache in those patients with decompression immediately by a fracture through the petrous portion of the temporal bone with release of spinal fluid and hemorrhage through the ear; in those with decompression by

multiple long linear fractures with spreading; and in those with decompression by early operations. Patients with decompression by operation suffer less with late symptoms in our practice, and this has been reported by others previously (Scudder<sup>2</sup>).

The symptoms are variable in degree. The headache is influenced by changes in the atmospheric pressure; it is aggravated by changes of the blood pressure within the cranium, and it is changed by sudden shifts in position of the head. All the influences effective suggest that its cause is a mobile and quickly changing element, namely, fluid. In no other medium, it seems to us, could the changes occur so rapidly.

These factors suggest strongly to us that the explanation for this post-traumatic headache will be found in an alteration in the normal circulation of the cerebrospinal fluid.

#### CONCLUSIONS

In ten patients with post-traumatic headache and dizziness, we have carried out lumbar air insufflation as suggested and described by Penfield. Our results confirm his, namely, that we have in this procedure a specific treatment for bona fide post-traumatic headache, if patients are properly selected. We have pointed out in our own failures some guides for this selection. We feel that we have in this treatment a great help in handling a large number of patients with cranial injuries, who have heretofore been most difficult to relieve and return to their normal occupation.

I wish to acknowledge the great assistance in treating these patients given by my partner, Dr. H. C. Lyman.

## NOTES ON THE BARBERS' HALL IN LONDON

J. PATERSON ROSS

Long ago, when London Wall was new, a walled or tunnelled passage connected the postern at its northwest corner with an outlying watch-tower called Barbican, or Burhkenning, referred to by John Stow as "being placed on a high ground, and also built of some good height, was in old time as a watch-tower for the city, from whence a man might behold and view the whole city toward the south, and also into Kent, Sussex and Surrey and likewise every other way, east, north, or west." The postern was known as Cripplegate, some think as a corruption of the word "crepulgeat," Anglo-Saxon for a covered way; but believed by others to be so called because of cripples begging there. Some confirmation of the latter theory is obtained from the account of how in the year 1010, for fear of the Danes, the body of King Edmund the Martyr was brought from Bury St. Edmunds "through the kingdom of the East Saxons, and so to London in at Cripplegate; a place so called of cripples begging there: at which gate, it was said, the body entering, miracles were wrought, as some of the lame to go upright, praising God."

Close to this same postern, in the thirteenth century, stood the Hermitage of St. James in the Wall. It belonged to the abbey and convent of Garadon, and housed, besides the hermit, two preaching friars, monks of the Cistercian Order. The hermitage obtained its supply of water from a well hard by, which came to be known as the monk's well.

In the course of time, the hermitage fell into disuse, and in 1381 the first mention is made of a hall being built on this site. Although the hermitage had disappeared, it was commemorated in the neighboring street, called Monk's Well Street, on the west side of which stood the Barber-Chirurgeons' Hall.

In 1634, another hall, designed by Inigo Jones, was built on the site of the first. It was surrounded by an old-world herb and physic garden, with sun dials and grape vines, which must have been a delightful place to walk in. This garden was useful as well as beautiful, for not only did it grow herbs for the old barber-surgeons' remedies, but it probably was responsible for keeping the flames at bay when almost all the other old city halls were burnt in the great fire of 1666.

Traces of these ancient buildings are still found in this odd little corner of London. From Aldersgate Street one may walk along the street called Barbican and, turning into Bridgewater Square, come to the place where the watch tower once stood. The square is surrounded

by warehouses, but in the center is a little fenced courtyard with seats and a shelter, frequented by the work people of the neighborhood.

Less than a quarter of a mile from the square stands the Church of St. Giles, Cripplegate, where John Milton, who once resided in Barbican, lies buried. Under the same roof are found the graves of John Foxe, the martyrologist, John Speed, the Elizabethan historian, and Sir Martin Frobisher, the sixteenth century explorer. In St. Giles', Oliver Cromwell wedded Elizabeth Bourchier in 1620.

In the adjoining churchyard is to be seen a stone bastion which strengthened the northwest angle of London Wall. Passing out of the churchyard into Hart Street, one may find a tablet marking the site of the Hermitage, and straight ahead is Monkwell Street. At first sight, it appears that nowhere in the world is buried treasure less likely to lie hidden; yet within a few yards, on the west side of the street, surrounded, covered over and well nigh concealed by warehouses, is a gateway marked "Barbers' Hall." Even after the hall has been found its importance may not be realized at once. Its exterior looks dull and humble, and it seems to be smothered by the ugly modern buildings which surround it on all sides. Yet here is, if not the cradle, at least the nursery of the craft of surgery in England (fig. 1).

To those who are not acquainted with the history of the ancient city guilds this may seem a strange statement, and a brief explanation of the rather curious relationship existing between the barbers and the surgeons may not be out of place.

In medieval times the clergy were the physicians; but, as time went by, they began to feel keenly the competition of Jewish physicians and lay surgeons. The Jews were thwarted by excommunication of their patients; but the only method the church could devise for dealing with lay surgeons was to brand surgery as an inferior and derogatory calling and to forbid the priests undertaking any operation which involved the shedding of blood. However, the priests were not content to let the control of surgery slip away so easily, and it occurred to them that their servants the barbers, who were known to be dexterous with sharp instruments, might not only shave their heads, but also be taught the surgical art under their direction. These pupils of the priests became barber-surgeons.

Quite distinct from the barber-surgeons, there existed a small guild or fellowship of surgeons, having sprung probably from a group of military surgeons trained in the Hundred Years' War (1337-1444). These men came of a better class, and their attainments were of a much higher order than the barbers. But their numbers being small—it appears that in 1491 only eight and in 1513 twelve persons, who were not ecclesiastics, were practicing surgery in London—they did not have any authority in the city. Quackery and malpractice were rife, yet the

surgeons were powerless to combat these abuses. In 1421, they combined with the physicians and sent a petition to King Henry V, praying him to control medical practice by ignorant men. The government did not give any assistance, so the Conjoint College of Physicians and Surgeons applied to the city for help.

In the meantime, however, the barbers practicing surgery became alarmed because they were included among the "ignorant men." The barbers, by this time, were well established as one of the ancient city

Fig. 1.—Barber-Surgeon's Hall, Monkwell Street, published Sept. 29, 1800, by John Manson, no. 6 Pall Mall.

companies, and they were strong enough to overcome the complaints of the surgeons, and not only did they draw up a code of laws (1450) in which they insisted on their right to practice surgery, but also, in 1462, a charter was granted by King Edward IV, ostensibly to the barbers, but actually in order to consolidate the position of the barber-surgeons.

Although this feud between the surgeons and the barbers practicing surgery must have been fierce, in time it seems to have died out, pos-

sibly because the surgeons felt that the only solution of the problem would be some form of union or compromise with their powerful antagonists. Whatever the explanation may be, such a union was completed in 1540 by a charter of King Henry VIII, the Company of Barbers and Surgeons being incorporated. It must be understood that this union did not make the surgeons either barbers or barber-surgeons, but it enabled the surgeons to obtain official control over the practice of surgery by the barber-surgeons. By the rules of the company, surgeons were not allowed to practice shaving; the barber-surgeons were not allowed to do more than draw teeth, and, if any of the latter became surgeons, it was only after some years of attendance at lectures and demonstrations and obtaining the bishop's license.

The terms and provisions of these old rules and charters are well worth reading. They show the growth of the sense of responsibility which surgeons felt in undertaking the care of their patients, and are based on the highest ideals of the duty of a practitioner to his patient. But in spite of all the efforts of these worthy men, the medical profession of these olden days must have been in a sad state of confusion, and it must have been extremely difficult for the common people to distinguish between impostors and honorable practitioners of medicine. That the chaotic condition remained for some centuries may be gathered from the account given by Walter Besant of the state of affairs in the time of George II.

The London citizen of the lower class never called in a physician unless he was in immediate danger; the herbalist physicked him, and the wise woman. Very often his own wife was an abyss of learning as to herbs and their properties, the bone-setter belonged to a distinct branch of the medical profession. There were apothecaries who prescribed as well as sold drugs. For instance, early in the century (18th), one Dalmahoy kept a shop on Ludgate Hill, where he sold, among other things, drugs, potions, electuaries, powders, sweetmeats, washes for the complexion, scented hair-oil pomades, dentifrices, love charms, Italian masks to sleep in, spermaceti salt, and scammony squills. And the doctor who wished to attract the confidence of citizens found a little stage management useful. He wore black, of course, with a huge wig; he carried a gold-headed cane, with a pomander box on the top; he kept his hands always in a muff, so that they might be soft, warm to the touch, and delicate; he hung his consulting room with looking-glasses, and he littered it with vials; he had on the mantlesheff a skull, and hanging to the wall a skeleton of a monkey; on his table stood a folio in Greek; and he preserved a Castilian gravity of countenance. Besides the physician, the apothecary, the herbalist, and the wise woman, there was a barber-surgeon. His pole was twined with colours three—white, red, and blue. But I know not how long into the century the alliance of surgeon and barber continued.

In 1745, the surgeons broke away from the barbers, formed the Surgeons' Company and became influential. In 1796, they forfeited their charter, and failing to obtain an Act of Parliament to reconstitute the company, they were incorporated by a charter of George III in 1800 as the Royal College of Surgeons of England.

The Royal College of Surgeons traces its descent from the early surgeons' guild and not from the barber-surgeons. But there was a middle period, lasting 200 years, when the surgeons and barbers were intimately associated, sharing a common home, Barber-Chirurgeons' Hall.

The building of the present hall was commenced in 1634, but some work must have been going on in 1668, for Pepys wrote on August 29: "And at noon comes by appointment Harris to dine with me: and after dinner he and I to Chyrurgeon's hall, where they are building it

Fig. 2.—The court room, erected by Inigo Jones in 1634.

new, very fine." The carved door-head at the entrance, with its curious armorials and grotesques in carved and painted oak, bears the date 1671. The hall must have been a goodly place in those days, and an illustration published as late as 1800 shows it a plain but dignified building with trees in the courtyard. At present, the exterior calls for little comment, but the interior of the court room is magnificent (figs. 2 and 3). It is an example of the best work of Inigo Jones, whose portrait by Vandyck hangs on the right of the doorway. It contains some fine furniture, and the plate of the company, the greater part of which has been in pawn from time to time in order to pay the royal levies, but

which has been almost entirely restored by rich benefactors. Among the pictures may be noticed the portrait of the Duchess of Richmond by Sir Peter Lely—her figure was adopted by the artist who designed the emblem of Britannia on the copper coinage of the country—and the portrait of Sir John Paterson by Sir Joshua Reynolds. Sir John was the clerk of the company at the time of the separation of the barbers from the surgeons.

Their most treasured possession, however, which deserves detailed study, is the great picture by Holbein of Henry VIII presenting the

Fig. 3.—Barber-Surgeons' Hall. The company admitting a new member.

charter to the combined Company of Barbers and Surgeons (fig. 4). The description of the persons represented in the picture was obtained from the paper on "The Worshipful Company of Barbers of London" by Mr. Frank Weston, F.S.A.

The picture is an oak panel, 10 feet long by 6 feet high, and is the largest of all Holbein's works. To obtain a fine surface, the oak was overlaid with gold leaf before it was painted, so it has never been subjected to the process of restoration. It shows the Palace of the Bride-

well, hung with tapestry, and the King on his throne evidently enjoying, in a cynical way, the pomp and display of fine robes, and the homage of his kneeling subjects, yet not condescending to look on them as, with his left hand, he "reaches" the statute to Thomas Vicary, his sergeant surgeon, who was master of the company. Some barbarian of a later age printed their names in white lettering on thirteen of these kneeling figures; and it may be this piece of vandalism that caused the incomparable Pepys to remark—"I did think to give 200 l for it, it being said to be worth 1000 l; but it is so spoiled that I have no mind to it, and is not a pleasant though a good picture."

Fig. 4.—Henry VIII presenting a charter to the Company of Barbers and Surgeons of London. From a painting by Holbein.

The figure on the extreme left of the picture (on the King's right hand) is Master J. Alsop, the King's apothecary, and next to him is Dr. William Butts, court physician, immortalized by Shakespeare in the play of *King Henry VIII*. Shakespeare lived for nearly ten years with a French Huguenot refugee named Christopher Mountjoy at the end of Monkwell Street, and he must have come to the hall to see this picture and study the portrait of Dr. Butts. Next the King is Dr. John Chambre, distinguished in his time in many offices, but most worthy to be remembered as one of the original founders, with Linacre, of the Royal College of Physicians of London.

Thomas Vicary, to whom the King is handing the charter, was surgeon to St. Bartholomew's Hospital, and the author of the first surgical treatise in English—"The Englishmans Treasure with the true Anatomie of Mans Body," published in 1548. He should be remembered not only as a surgeon, but as one who had the training of surgeons at heart; and had surgical education been carried on as he proposed, the standing in society of English surgeons would have been much higher. He laid down that a surgeon "ought to be learned and that he know his principles, not onely in Chirurgerie, but also in Phisicke, that he may the better defend his Surgery; Also he ought to be scene in natural Philosophie, and in Grammar, that he speake congruitie in Logike, that teacheth him to prove his proportions with good reason. In Rethorike, that teacheth him to speake seemely and eloquently; also in Theorike, that teacheth him to know thinges naturall, and not naturall, and thinges agaynst Nature. Also he must know the Anatomie, for al Authors write agaynst those Surgions that worke in mans body not knowing the Anatomie, for they be likened to a blind man that cutteth in a vine tree, for he taketh more or lesse than he ought to doo."

Next to Vicary is Sir John Ayliff, a famous surgeon, and then Nicholas Simpson and Edmund Harman, King's barbers. The latter was a most important personage, as may be inferred from his gold chain, and through court influence he acquired a great estate. Several of those seen in the picture were left legacies of 100 marks by Henry, but Harman was esteemed so highly that he was named one of the King's executors, and received a legacy of 200 marks.

The fifth figure is James Monforde, King's surgeon, and next to him John Pen, King's barber, whose wife, Mistress Lucy Pen, nursed the young King Edward VI until he died. Her ghost is said to walk the long gallery at Hampton Court on moonlight nights, and the sound of her spinet is then heard.

Nicholas Alcocke and Richard Ferris, both surgeons, complete the list of prominent members of the united company shown in the picture.

There is a committee room on the first floor which also contains many valuable and interesting pictures, and on the other side of the landing is a window which looks out on the site of the Anatomy Theatre, now replaced by warehouses. The teaching of anatomy was one of the most important functions of the Company of Barbers and Surgeons, and the demonstrations were carried out with great ceremonial. Among the lecturers was Dr. John Caius, founder of Caius College in Cambridge. He lived in Bartholomew's Hospital, though he was not a member of the staff; and, for the twenty years during which he held the appointment, he might have been seen on Tuesday afternoons walking out of the Little Britain Gate of the hospital, across the Close and through Jewin Street to the hall.

By Act of Parliament the barber-surgeons were entitled to take the bodies of four condemned persons yearly for anatomy, but there was often considerable difficulty in obtaining them. The beadles had to attend at Tyburn for dead bodies once a quarter, and many were the unseemingly fights there. Often when the beadles had secured their body and driven off in a coach they were attacked and beaten, and the body rescued by friends. The hangman also had to be "squared," and the account books of the company show receipts for the hangman's Christmas box.

Tales innumerable might be culled from the old records, but these notes must come to an end. Let them conclude with a story which surely caps any exploits of the resurrectionists. In the year 1740, one of the malefactors hanged at Tyburn revived after being brought to the hall for dissection. It was supposed that the letting of blood helped to revive the corpse; the poor fellow cried several times, loudly, "Don't." It was an awkward affair. Having been hanged once, he could not be hanged again, so he was nursed, and, after the administration of warm wine and other restoratives, the surgeons and doctors present packed him off and paid his passage in a ship going to the East. William Duell, the convict, changed his name to William Devrall, and flourished as a Levant merchant. Out of gratitude, he sent the old screen of stamped and gilded Levant leather which may still be seen in use, to convince even the more incredulous of the truth of this story.

# TRANSFUSIONS IN ACUTE LOSS OF BLOOD\*

CLARENCE E. BIRD

An active neurosurgical clinic in which tumors of the brain are removed daily provides an unusual opportunity to observe the effects of transfusion in patients urgently in need of blood. In the majority of these patients there is no complicating factor, i.e., no traumatic shock, sepsis, primary cardiac or vascular disease; in other words, the body is, in most instances, essentially normal except for the presence of the tumor.

Exploratory operations and the partial, subtotal or complete removal of several types of tumors are, as a rule, accompanied by little loss of blood. Examples are operations on the gliomas, pituitary adenomas and the usual cerebellar tumors. Cerebral explorations without the removal of tumor, decompressions, ganglionectomies and the removal of old clot in *pachymeningitis hemorrhagica interna* are not exsanguinating operations.

In sharp contrast to these relatively bloodless procedures lie the radical extirpations of meningiomas and hemangiomas, particularly the more extensive operations latterly carried out by electrosurgical methods.<sup>1</sup> The essential factors for successful removal in all of these procedures are, first, the adequate control of hemorrhage, and second, the prompt replacement of any large amount (from 400 to 1,500 cc.) of blood lost. Angiomas are highly vascular by nature, and meningiomas acquire, as they invade or surround brain, bone or other anatomic structures, extensive vascular connections. Furthermore, in both, the peripheral blood supply is increased, so that the vessels of the surrounding tissues—scalp, thickened skull, dura, leptomeninges and vessels of willisian and galenian derivation—are often enormously increased in number and caliber. Operative removal is painstaking and tedious, the procedures, single stage or multistage, consuming from four to nine hours in all cases.

Though loss of blood may occasionally be sudden and severe, with rapid increase in pulse rate, inability to palpate the radial pulse and drop of blood pressure to an undetectable level (as may occur when a vascular bone flap is broken back from a weeping dura or when a large vessel is opened and is secured only with difficulty), the loss is usually gradual.

\*From the Surgical Clinic of Dr. Harvey Cushing, the Peter Bent Brigham Hospital, Boston.

\*In this study, Miss Louise Melanson, R. N., for ten years associated with the Peter Bent Brigham Hospital and for over five years attached to Dr. Cushing's Operating Room Force, has been of greatest assistance.

1. Cushing, Harvey: Macewen Memorial Lecture on the Meningiomas Arising from the Olfactory Groove and Their Removal by the Aid of Electro-Surgery, *Lancet* 1:1329 (June 25) 1927.

Chart 1, an anesthesia record, illustrates the usual level course of the record of the pulse and blood pressure during a comparatively bloodless craniotomy.

## REPORT OF CASES

The case was that of a captain in the navy, aged 51, from whom a large (170 Gm.), left occipital, parasagittal meningioma was removed at a single operation under procaine hydrochloride anesthesia. The blood pressure throughout this procedure remained between 120 systolic and 60 diastolic and 80 systolic and 40

Chart 1.—Record kept during removal of meningioma. Adequate hemostasis. No significant change in pulse rate or blood pressure. A "level" chart. In this and the following charts, the line labeled *P* here indicates pulse rate; *R*, respiratory rate; *S*, systolic blood pressure; *D*, diastolic blood pressure.

diastolic, and the pulse rate between 60 and 88. One liter of tap water was absorbed by rectum during the five hour operation.

Chart 2 shows the effect of acute hemorrhage at the time of elevation of a bloody bone flap.

A left suprasylvian meningioma was removed in a single stage under procaine hydrochloride and ether anesthesia from a woman, aged 40, whose record is shown. As the flap was elevated there was sharp hemorrhage with almost immediate

(1) rise in pulse rate, (2) loss of radial pulse, so that the count was necessarily made at the femoral artery, (3) drop in recordable blood pressure to "zero"<sup>2</sup> and (4) disturbance in respiration (air-hunger with shallow, rapid respirations). The sharp hemorrhage was shortly controlled by the free use of large flat pieces of muscle (from an adjacent amputation of a breast), large cotton pads wet with warm physiologic sodium chloride solution, and silver clips and endothermy current to stop obvious bleeding points. There resulted a prompt recovery of blood pressure, pulse strength and pulse rate to a satisfactory level somewhat approaching that before elevation of the flap. Within an hour the pressure had again fallen off

Chart 2.—Record of removal of meningioma. Sharp hemorrhage on elevation of bone flap. Spontaneous recovery of vascular efficiency. Secondary rise in pulse and fall in pressure to "zero" for three hours. Transfusion with recovery.

to zero and remained so over a period of three hours. During this time the meningioma was removed; a small refusion of the patient's own blood collected under sterile conditions by suction from the operative field was given;<sup>3</sup> and finally, a transfusion of 500 cc. of whole blood was carried out.

2. The pressure, of course, does not reach zero. However, it becomes too low to be detectable with the clinical sphygmomanometer. Throughout the paper, references to "zero" pressure should be so interpreted.

3. Davis, Loyal E., and Cushing, Harvey: Experiences with Blood Replacement During or After Major Intracranial Operations, *Surg. Gynec. Obst.* **40**:310, 1925.

It is astonishing that a patient could go for three hours without detectable blood pressure and emerge without evidence of damage to nervous tissue. The transfusion quickly brought the pulse rate down, increased the pulse strength (as indicated by the ability to count the pulse at the radial artery) and brought the blood pressure up to a readable level.

Charts 3 and 4 show the effect of long continued, gradual loss of blood.

Chart 3.—Record of removal of meningioma. Effect on pulse, respiration and blood pressure of long-continued, gradual loss of blood. Prompt improvement following transfusion. (See also chart 7).

The first is an anesthesia record of a man, aged 45, from whom a bilateral meningioma of the olfactory groove was removed in a one-stage operation under procaine hydrochloride and ether anesthesia. Small amounts of blood were continually lost over a period of three and one-half hours until the pulse rate began to rise from 10 to 15 beats a minute and the pressure, which began at 130 systolic and 60 diastolic, gradually assumed a level of 70 systolic and 40 diastolic. The pulse pressure had declined from 70 to 30. This condition prevailed for another hour, at which time the pulse rate continued to rise steadily and the pressure

dropped to a barely perceptible 30 systolic and finally to zero. The pressure remained at a level too low to be recorded for thirty minutes during which 500 cc. of blood was given, producing a promptly favorable reaction, with a drop in pulse rate of from 190 to 120 and a rise in blood pressure of from zero to 60 systolic and 30 diastolic.

Chart 4 is a similar record. During the first three hours of this difficult extirpation of a meningioma under procaine hydrochloride anesthesia, in a woman, aged 32, the pulse rate gradually rose from 108 to 140. The blood pressure behaved in an unsteady manner due to repeated losses of considerable amounts of blood

Chart 4.—Record of removal of meningioma. Effect on pulse, respiration and blood pressure of long continued loss of blood. Same effect as shown in chart 3.

The spontaneous recoveries of vascular tone which are to be noted occurred during temporary hemostasis. The total loss of blood, however, resulted in a lowering of pressure from 130 systolic and 60 diastolic to 80 systolic and 60 diastolic (a drop in pulse pressure of from 70 to 20) and in a steady rise in pulse rate.

During the fourth hour, the pulse rate continued to rise, and as the tumor was rotated out of its bed and before the field could be made dry, the final loss of blood caused a further rise in pulse rate to 164, with weakening of the impulse (which could now be palpated only at the femoral artery) and a sharp drop in pressure to a level which could not be recorded. As frequently occurs during profound drops in blood pressure, the patient vomited.

After fifteen minutes of zero pressure readings a transfusion of 370 cc. was given, immediately restoring the blood pressure to a safe level (95 systolic and 75 diastolic), lowering the pulse rate and strengthening its impulse.

However, it should be noted that an improvement, though not so dramatic, many times occurs without transfusion or with the aid of a small transfusion as a "starter."

Chart 5 is the record of the second operation of a two-stage removal of a right parietal meningioma, under procaine hydrochloride anesthesia, from a woman

Chart 5.—Record of effect of sharp hemorrhage as a vascular meningioma was rotated out of its bed, showing beginning spontaneous recovery of vascular tone before transfusion.

aged 29. It will be noted that following the removal of a large mass of tumor there was persistent hemorrhage with a prompt rise in pulse rate to 160 and a drop of blood pressure, over a period of one-half hour, to zero. The pulse was then palpable only at the femoral artery and the pressure remained at zero for one hour and ten minutes. After the first forty minutes of this time, however, the pulse dropped 10 points in rate, definitely indicating a tendency to improvement. It was only after one hour and five minutes of pressure too low to be recorded that 300 cc. of blood was given. This appears to have aided the recovery of circulatory efficiency, though the improvement might well have occurred spontaneously.

A second example illustrating the ability of the circulation to recover efficiency after bleeding, provided fluid is available, is to be seen in chart 6.

An Italian woman, aged 46, had a left parietal meningioma arising from the falx. The surrounding scalp, calvarium and dura were excessively vascular, and the exposure was bloody. Sharp drops in blood pressure to a level too low to be recorded, with marked weakening of the pulse but without accompanying rise in pulse rate, occurred. The original drop in pressure followed acute hemorrhage at

Chart 6.—Record of repeated hemorrhages with sharp drops in pressure. Spontaneous recoveries of vascular tone. Slow pulse, usually indicating reserve and ability to recover tone if fluid is available. Transfusion probably not necessary, though desirable.

the time the bone flap was elevated. Thereafter, for two hours and fifteen minutes, during which time the tumor was removed, there was an unstable circulation, with a constantly low pulse pressure and a total pressure dropping off to zero twice.

The patient was supplied with fluid by rectum throughout the procedure and was on the way toward recovery of pressure to a safe level, when a transfusion of 300 cc. was given which evidently accelerated the improvement. Procaine hydrochloride and ether anesthesia was used.

On the other hand, a large transfusion may be necessary to insure recovery if the blood volume has been greatly decreased either from sudden or gradual loss of a large amount of blood.

Chart 7 is the anesthesia record of a two-stage removal of a right frontal meningioma weighing 75 Gm. from a Russian Jewish housewife, aged 47. At each session there was a gradual rise in pulse rate (from 90 to 165 at the first operation and from 90 to 138 at the second), with weakening of the impulse and a drop in blood pressure from 115 systolic and 60 diastolic to zero on the first occasion, and from 120 systolic and 75 diastolic to zero at the second. The marked weakening

Chart 7.—Record of two-stage extirpation of meningioma. Gradual loss of blood with rise in pulse and dropping off of pressure at each operation. Prompt recovery of vascular efficiency after transfusions.

of the pulse and high pulse rate probably, though not certainly, indicated a degree of circulatory failure from which spontaneous recovery would not occur. A transfusion of 600 cc. of blood at the first operation and of 500 cc. at the second quickly restored the pulse rate and blood pressure to approximately normal levels. For the first operation, procaine hydrochloride and rectal ether anesthesia were used, and for the second operation procaine hydrochloride.

When the pulse rate does not rise with a fall in blood pressure there is usually a prompt return of pressure after the bleeding has stopped. In these circumstances, the loss in blood volume may be just sufficient to

cause a drop in pressure without, however, stimulating the heart to an increased rate for the purpose of increasing its minute output.<sup>4</sup> The heart, in other words, is probably strong enough to compensate for the loss of blood by increasing its output per beat and does not call on the added mechanism of acceleration. In chart 6, for example, the pulse rate is surprisingly low considering the large amounts of blood lost. The recoveries of vascular tone without the aid of transfusion are prompt, probably due both to an efficient heart and to readily available rectal or subcutaneous fluid. Persons vary, however, in their circulatory reactions, and the failure of rise in pulse rate may give to the operator a false sense of security.

The effect of repeated small transfusions in sustaining the blood pressure during a long operation is seen in chart 8.

From a woman, aged 27, a deep-seated meningioma of the falx was partially removed in two stages. The chart is the anesthesia record from the second operation, which was performed under procaine hydrochloride. As will be noted, four small transfusions, totaling 630 cc., were given over a period of seven hours' operating. The first blood was provided during a spontaneous improvement. The other transfusions each had a definite effect, raising the blood pressure to a satisfactory level. However, each transfusion had less effect than the one preceding, and in the end the patient, after a long, desperate procedure, left the operating room with no recordable pressure and eventually died on the tenth postoperative day with subacute meningitis (*Streptococcus hemolyticus*).

#### COMMENT

During operations for intracranial tumor patients have been observed who, though their blood pressure remained too low to be recorded for from thirty minutes to three hours, recovered after spontaneously "picking up" or following transfusion, without detectable injury to nervous tissue or other permanent ill effect.

It is undoubtedly true, however, that during this time these patients are well within a danger zone in which increase in blood volume is desirable. During depletion of the blood volume, the compensatory mechanisms for maintaining efficient circulation have operated, i.e., (1) peripheral vasoconstriction, (2) transfer of fluid from tissues to blood stream, partially making up blood volume, (3) increased stroke output of the heart, (4) increased heart rate and (5) (as has been shown by Barcroft<sup>5</sup> and though probably unimportant in this connection) transfer of red blood corpuscles from the spleen to the circulating blood stream. Eventually, however, a point is reached at which the minute cardiac output is decreased below a safe level.<sup>4</sup> A sustained increase in blood

5. Barcroft, J.; Harris, H. A.; Orahovats, D., and Weiss, R.: A Contribution to the Physiology of the Spleen, J. Physiol. **60**:443, 1925.

volume will increase the minute cardiac output, for if the strength of the myocardium is unimpaired, the heart needs only an adequate supply of fluid to allow it to pump efficiently.

This fluid may be added to the blood stream in the form of physiologic sodium chloride solution or Ringer's fluid, gum acacia solution, refusion of the patient's own blood (collected by a sucker at operation),<sup>3</sup> or best, whole blood transfused from a suitable donor. While the provision of an adequate supply of fluid by rectal infusion or hypodermoclysis during

Chart 8.—Record of removal of meningioma. Repeated transfusions, each less effective than the one preceding. (See also chart 9).

a long bloody operation is highly desirable or even necessary, it is well recognized that saline solution or Ringer's solution given intravenously has only a transitory effect in raising blood pressure. Gum acacia of a suitable osmotic pressure to sustain blood pressure contains more calcium than is desirable for injection,<sup>6</sup> and Drinker<sup>7</sup> has recently shown

6. McLeod, J. J. R.: *Physiology and Biochemistry in Modern Medicine*, ed. 4, St. Louis, C. V. Mosby Company, 1922, p. 142.

7. Drinker, Cecil K.: Personal communication to the authors.

that acacia solutions made up according to the directions of Bayliss do not possess either the chemical or the physicochemical appropriateness ascribed to them by that author.

Also, epinephrine and ephedrine have uncertain actions when there is acute loss of blood,<sup>4</sup> though the use of ephedrine as a temporary expedient is justified and is not accompanied by the rapid depression of the circulation which occasionally ensues secondarily after the injection of epinephrine.

On the other hand, the patient's own collected blood and whole blood from a suitable donor have the requisite osmotic pressure and viscosity to maintain blood volume, therefore sustaining the minute cardiac output (the requisite of circulatory well-being), indicated clinically by a rise in blood pressure to a recordable level and by the slowing and the strengthening of the pulse.

Replacement of the patient's own blood has been found on rare occasions to produce a sharp and alarming fall in pressure instead of the expected rise. Even though this fall is transient and is followed by marked improvement, the possibility of failure in an emergency has led to the use of whole blood transfused directly. This is done by any one of several well-known methods—Kimpton tubes, Lindeman syringes, Head pump, etc.

During 1927, 297 major neurologic operations were performed at the Peter Bent Brigham Hospital, by far the greatest number for tumors of the brain. Fifty-two transfusions were carried out in the hospital, and of these twenty-four were given to twenty neurologic patients, there being four repeated transfusions at second-stage operations. Fifteen of the twenty patients had meningiomas and of the other five, one had a metastatic carcinoma to the falx (probably from the lung), one a basal fracture (a child with subdural hemorrhage), one a cerebellar ependymblastoma, one a cerebral spongioblastoma multiforme and one a cerebral tuberculoma with tuberculosis of the suprarenal glands.

For patients in whom the possibility of a "wet" operation is foreseen, blood from a donor, relative or professional, is grouped and cross-matched the evening before operation, and the donor is present in or near the operating room throughout the procedure. Blood can then be given within twenty minutes. If a particularly bloody bone flap is turned back, a transfusion may be begun immediately, the donor and recipient already having been prepared. In all cases the recipient's cephalic or internal saphenous vein has been directly isolated through an incision, for possibility of failure to give blood cannot be countenanced in these critical cases. Transfusions, of course, are never given before the falling off of pressure because of the resulting increase in bleeding

and the possible embarrassment of the heart from abnormally increasing the blood volume.

Reactions to transfusion have been essentially absent in spite of the fact that the patients have received from 250 to 1,500 cc. of blood during a procedure and in several instances have been given blood from two or even three donors. One patient had a mild twenty minute chill on the table thirty-five minutes after a transfusion of 300 cc. (chart 6). There

Chart 9.—Record of removal of meningioma. Repeated transfusions, each less effective than the one preceding. (See also chart 8).

was no fall in blood pressure with this disturbance, though the pulse rate rose from 120 to 140.

It has been a constant experience that whereas an initial fall in pressure to zero is promptly recovered from by blood replacement, the second, third and subsequent falls in pressure are not so well borne and are less and less responsive to transfusion. This is well shown in chart 8 and in the anesthesia record of a woman, aged 44, from whom a cerebellar meningioma was removed (chart 9).

After continued loss of blood, this patient showed the usual signs of circulatory failure with a rise in pulse rate of from 80 to 140 and a lowering of blood pressure to a barely perceptible 45. Transfusion of 250 cc. of blood promptly lowered the pulse rate to 90 and raised the pressure to 78 systolic and 60 diastolic, a level 45 mm. lower than before the primary drop. Continued bleeding brought restlessness and another rise in pulse rate to 120 and a fall in blood pressure to zero. A second 250 cc. of blood restored the pulse to 105 and the pressure to 70 systolic and 55 diastolic, a still lower level. However, in spite of the fact that there was no more bleeding, the effect of the second transfusion was only transitory, and another 100 cc. was necessary to restore the circulation to a safe level. This was accomplished, as indicated by the operative and postoperative notes, although a graphic record cannot be given as the chart on which the entries were made has unfortunately been destroyed.

In such a case the mechanisms for sustaining a competent circulation (other than maintenance of proper blood volume) are probably progressively exhausted, i.e., peripheral vasoconstriction is lessened, and the cardiac musculature becomes weakened. This presumably explains the failure of the circulation to regain its tone completely for from two to ten days or more in some cases following a protracted procedure.

Transfusions are rarely needed in neurologic operations on children. Their intracranial lesions cause little bleeding, as a rule. This is most fortunate, for the younger patients usually have a rapid pulse rate and a low blood pressure from the beginning of the procedures and would quickly require blood replacement if any considerable bleeding occurred. Transfusion is also inconvenient in the cerebellar position, in which most of these small patients must be placed.

# THE EFFECT OF SURGICAL SOLUTION OF CHLORINATED SODA (DAKIN'S SOLUTION) IN THE PERICARDIAL CAVITY\*

CLAUDE S. BECK

Within recent years surgical solution of chlorinated soda (Dakin's solution) has been used to irrigate the pericardial cavity in the treatment of purulent pericarditis. There has been no agreement of opinion concerning its effect in these cases. It is my purpose in this report to show experimentally the effect of surgical solution of chlorinated soda in the pericardial cavity. This solution has won for itself a place of great value in the treatment of certain forms of infection, but its indiscriminate use is not devoid of danger. In the abdomen it produces an inflammatory reaction,<sup>1</sup> and when brought into contact with normal intestine, it produces perforation of the wall. The cases of pericarditis in which surgical solution of chlorinated soda was used are reviewed to determine if possible the effect that the solution might have had.

In the case reported by Pool<sup>2</sup> "two Carrel tubes . . . were inserted (into the pericardium) about five inches. Dakin's solution was introduced very slowly by gravity; 10 cc. every hour through each tube. The wound was dressed daily . . . tubes being removed and fresh tubes reinserted." By the fifth day after operation the discharge was "thin and mucoid, not purulent. Only one Carrel tube introduced." On the tenth day there was a "moderate discharge from the pericardium." The abdomen became distended and edema of the face, scrotum, legs and abdomen developed. On the fourteenth day the pulse was "of good quality. Not dyspnoeic. Oedema of face and legs less." By the twenty-fourth day "the oedema was practically gone. Small irrigation catheter passes inward four inches. Cavity held only about 2 cc. Marked pulsation of whole precordial region. It was believed that the oedema was due to myocarditis." The pericardial cavity continued to drain small amounts for about another month. There was "no retraction of the chest wall with systole. . . . No murmur heard." The electrocardiogram showed "right ventricular pre-

G.: Neutral Solution of Chlorinated Soda (Dakin's Solution) in the Peritoneal Cavity: An Experimental Study, *J. A. M. A.* 70:840 (March 23) 1918.

2. Pool, E. H.: Pericardiotomy for Suppurative Pericarditis. *Ann. Surg.* 73:393, 1921.

dominance . . . probably due to the mechanical difficulty which this ventricle meets in contracting; possibly as the result of adhesions." When seen eight months after the operation, "the boy was apparently in normal health and was able to exercise as before the operation without embarrassment." "In another case," quoting Pool, "I should begin the Carrel-Dakin method at once. It was here undertaken with some trepidation because it had apparently never been employed in the pericardium and I was uncertain as to its effects. Yet its indications seemed to demand it. On the basis of a former experience and the study of case reports, it was felt that thick pus with fibrin was likely to wall off the cavity into chambers, resulting in retained excretions and imperfect drainage, especially of the left recess. It was believed that the solvent effect of Dakin's solution would obviate this risk and would soon render the excretions thin and less in volume, besides gradually sterilizing the cavity. Practice confirmed the theory. Improvement was striking and sustained. The solution apparently exerted no noxious influence upon the pericardium and may, I think, be employed with confidence and advantage in subsequent cases."

In a discussion of Pool's paper, Jopson<sup>3</sup> reported a case of purulent pericarditis in which he used the Carrel-Dakin treatment. "The Dakin solution was badly borne in the pericardium and caused cardiac embarrassment, the fluid apparently being too thick and gelatinous after mixing with the pus and it had to be given up." Bransfield<sup>4</sup> introduced 1 ounce of Dakin's oil daily into the pericardial sac in his case, and after the drainage ceased, there seemed to be "no cardiac involvement." Auchincloss<sup>5</sup> referred to a case in which irrigations with surgical solution of chlorinated soda were carried out and "at autopsy adhesions (between the heart and pericardium) were found but there was no accumulation of pus in the pericardial sac."

In the case reported by Wood and Bradley,<sup>6</sup> irrigation of the pericardial cavity with surgical solution of chlorinated soda was begun on the third day after the operation. It was stated that "the general condition remained unchanged. The discharge (next day) was still scant. The sac was again irrigated with Dakin's solution. There was on the following day a thin purulent discharge, the tube was reintroduced and Dakin's irrigations repeated." In a few days the wound was healed.

6. Wood, Alfred C., and Bradley, W. N.: *Purulent Pericarditis in Childhood*, *Atlantic M. J.* **28**:436, 1925.

Three weeks after operation "the pulse was 100, full, regular. Heart sounds normal in quality and intensity."

Stone<sup>7</sup> operated on a patient in whom "the pericardium was irrigated daily, first with normal physiologic sodium chloride, then after a few days with half strength and finally with full strength surgical solution of chlorinated soda. . . . The daily irrigations came away practically clear. . . . In a letter several weeks afterwards, the patient reported himself practically well." In one of the cases reported by Williamson,<sup>8</sup> irrigation of the pericardial cavity with surgical solution of chlorinated soda was carried out. The patient recovered with "no evidence of faulty action of the heart."

Klose and Strauss<sup>9</sup> expressed the belief that if the pericardium is irrigated at all, only a physiologic solution of sodium chloride should be used. Peterson,<sup>10</sup> in a report of three cases of suppurative pericarditis in none of which surgical solution of chlorinated soda was used, stated that, "there should not be any fixed rules about irrigation of the pericardium or about the placing of drainage material in the sac." In a discussion of these cases, Whittemore<sup>11</sup> stated that he did not "see any reason why the solution (Dakin's) should not be used." Roberts<sup>12</sup> likewise sees no good reason to suppose that irrigations with a mild antiseptic cause any cardiac disturbance.

It seems from the foregoing statements that the effect of surgical solution of chlorinated soda has not been sufficiently striking to justify a conclusion concerning its value in the treatment of purulent pericarditis.

#### EXPERIMENTS

The following experiments were carried out on dogs to show the effect of surgical solution of chlorinated soda in the pericardium. In each experiment the dog was given a dose of morphine and then was anesthetized with ether through an intratracheal catheter inserted through the larynx. Mechanical respiration was carried on by means of the Erlanger apparatus. After the operative field was carefully prepared, about 5 cm. of the fifth rib on the left was resected sub-

periosteally. Before completing the operation, the air was expelled from the chest, and the pleural space was completely closed. Morphine was administered to the dog after the operation. For the specimen, the dog was killed by chloroform narcosis. The surgical solution of chlorinated soda was full strength, and carefully titrated according to the standard procedure by the hospital pharmacist.

*SERIES 1.—Effect of continuous irrigation of the pericardial cavity with surgical solution of chlorinated soda.*

EXPERIMENT 1 (dog 25): The dog weighed 17 Kg. The pericardium was sutured to the thoracic wall, leaving an opening into the pericardium about 2 cm. in diameter. The pleural space was completely closed. A small catheter was introduced into the pericardium about 4 inches (10.16 cm.) and sutured in place to the wound. The end of the catheter was connected to an irrigating bottle, and after the dog came out of the anesthetic surgical solution of chlorinated soda was allowed to flow slowly into the pericardium. Immediately on starting the irrigation, the dog aroused from his sleep and appeared to be in acute pain. One-half grain (0.0325 Gm.) of morphine was given but this did not stop the pain. Bloody froth trickled from the pericardium. An hour later, one-half grain of morphine was given again, but because of the acute pain the experiment was terminated by chloroform narcosis. About 300 cc. of the solution had been used, and as it returned from the pericardium, it had the appearance of blood. The pericardial cavity at necropsy contained clotted blood. The surface of the pericardium was studded with bleeding points representing eroded blood vessels.

Repetition of this experiment gave a similar result.

*Comment.*—The pain produced by surgical solution of chlorinated soda in the normal pericardium of the dog was severe. Hemorrhage was produced by erosion of the small vessels. The absence of pain and hemorrhage in the human cases of purulent pericarditis already referred to was probably due to a layer of fibrin, which in those cases acted as a protective membrane to the surface of the pericardium.

*SERIES 2.—Effect of a small quantity of surgical solution of chlorinated soda injected into the pericardial cavity.*

EXPERIMENT 2 (dog 5): This animal weighed 17.5 Kg. The pericardium was exposed, and 40 cc. of surgical solution of chlorinated soda at a temperature of 38 C. was injected into it through a small aspirating needle. The heart immediately increased its rate. The following day the dog appeared to be very sick with a temperature of 39.8 C.; pulsus paradoxus was present. The cardiopericardial roentgenogram increased 1 cm. in its transverse diameter following operation. The dog died thirty-six hours after the surgical solution of chlorinated soda was injected into the pericardium. At necropsy, 300 cc. of blood-tinged fluid was found in each pleural cavity. The pericardium contained 110 cc. of dark hemorrhagic fluid. The pericardium was edematous, hemorrhagic, and in several small areas it was eroded and almost perforated. There were no adhesions between the heart and pericardium, but a shaggy pericarditis was beginning to form (fig. 1). The fat over the mediastinal surface of the pericardium was edematous and the edema extended along each vena cava. The abdomen contained 250 cc. of clear fluid. The liver was congested. Between the lobes of the liver was a layer of fibrin several millimeters in thickness.

EXPERIMENT 3 (dog 8): The animal weighed 10.4 Kg. The pericardium was exposed, and 40 cc. of surgical solution of chlorinated soda at a temperature of 38 C. was injected into it through a small aspirating needle. After 20 cc. was injected, the pulse rate increased from 60 to 208 per minute. The fluid in the pericardial cavity became a bloody foam. A roentgenogram of the heart and pericardium taken before the operation measured 7.6 cm. in the transverse diameter. The following day the respirations were somewhat labored and the pulse rate was 140 per minute. The cardiac sounds could not be heard. One week after the operation, the dog seemed to be in good condition. The cardiac sounds were faintly heard; the pulse rate was 132 per minute, and a roentgenogram of the heart and pericardium measured 8 cm. in its transverse diameter. Thirteen days after the operation, the dog was in good condition. The first cardiac sound was a little roughened but no definite murmur was heard. The dog was killed. There was no free fluid in the chest or abdomen, no edema of the tissues. The pericardium was everywhere adherent to the heart. In places these adhesions were fibrous; elsewhere they could easily be separated by the finger (fig. 1). The pericardium contained about 10 cc. of clear fluid.

EXPERIMENT 4 (dog 2): The animal weighed 17.6 Kg. July 9, 1928: A roentgenogram of the heart and pericardium taken before the anesthetic was started measured 8.4 cm. in the transverse diameter. The pericardium was exposed, and through a small aspirating needle 15 cc. of surgical solution of chlorinated soda was introduced. The pulse rate increased immediately from 164 to 268 per minute. Through the aspirating needle, 20 cc. more of the solution was injected. The fluid in the pericardial cavity became blood-tinged. A roentgenogram of the heart and pericardium taken after the operation was completed measured 9.3 cm. in the transverse diameter, and one taken the following day measured 9.6 cm.

July 11: The general condition seemed to be good; the pulse rate was 152 per minute; cardiac sounds were not audible.

July 13: The pulse rate was 144 per minute; cardiac sounds were heard faintly; there was no evidence of fluid in the chest or abdomen; the transverse diameter of the heart and pericardium was 9.8 cm.

July 20: The pulse rate was 140 per minute; a systolic murmur was heard over the left side of the chest; slight edema of the scrotum was noted.

July 26: The dog weighed 22.2 Kg.; fluid was present in the abdomen and chest; the transverse diameter of the heart was 9.8 cm.

July 31: The dog weighed 24.8 Kg. The abdomen was markedly distended and the edema was generalized; the respiratory rate was 36 per minute; pulsus paradoxus was present.

August 6: The dog died. The soft tissues of the entire body were markedly edematous. The abdomen contained 4 liters of blood-stained fluid and each pleural space contained 1 liter. The pericardium contained 300 cc. of dark, blood-stained fluid. The pericardium was thickened and was not adherent to the heart. Around the base of the heart were some wartlike excrescences from which bleeding occurred. The surface of the pericardium was roughened (fig. 1). The lungs and liver were congested. The heart itself was smaller than normal because of the pericardial tamponade.

EXPERIMENT 5 (dog 124): The dog weighed 14.2 Kg. June 4, 1928: An opening 1 cm. long was made in the pericardium, and surgical solution of chlorinated soda at a temperature of 38 C. was dripped on the heart. The pericardial fluid became turbid and flakes of fibrin precipitated. The pulse rate did not increase. After a few minutes the fluid became bloody and active bleeding from

the pericardium occurred. In all about 60 cc. of the solution was used and about 80 cc. of the blood-stained mixture was removed. The opening in the pericardium was sutured. Four hours after the operation was completed, the cardiopericardial roentgenogram increased 6 mm. in the transverse diameter. This increase in size was undoubtedly due to hemopericardium. During the first two days after opera-

Fig. 1 (experiments 2 to 5).—Showing the effect of small quantities of surgical solution of chlorinated soda injected into the pericardial cavity.

tion the cardiopericardial shadow increased slightly in size and then gradually returned to its preoperative size. The cardiac sounds were not audible.

June 9: The dog was in good condition; it was killed. There were no signs of circulatory failure. The organs, except the heart and pericardium, appeared to be grossly normal. The surface of the pericardium showed areas of ecchymosis.

Generalized fibrinous adhesions between the heart and pericardium were present together with small clots of blood and in places a gelatinous exudate (fig. 1).

EXPERIMENT 6 (dog 103): The dog weighed 16.6 Kg. May 10, 1928: An opening about 4 mm. long was made in the pericardium and a soft rubber catheter was inserted into the pericardial cavity. Small quantities of surgical solution of chlorinated soda were introduced through this catheter into the pericardial cavity. Almost immediately the fluid became bloody and the pulse rate increased. Over a period of seven minutes, 30 cc. of the solution was used. The pericardial cavity was then irrigated with physiologic solution of sodium chloride which when drawn off looked like pure blood. Active bleeding was taking place, and after the pericardium was closed, it was feared that cardiac tamponade would develop.

During the succeeding days the dog was in good condition. The size of the cardiopericardial roentgenogram did not change perceptibly. There were no cardiac murmurs and there was no edema. The dog was killed on July 24, 1928. A generalized adhesive pericarditis was present. The pericardial space was obliterated (fig. 2). There was no fluid in the pericardium.

EXPERIMENT 7 (dog 93): The dog weighed 17.3 Kg. May 17, 1928: An opening 5 mm. long was made in the pericardium and a soft rubber catheter was inserted into the pericardial cavity. A few cubic centimeters of surgical solution of chlorinated soda was introduced through the catheter. The pulse rate increased from 140 to 180 per minute. The fluid was then aspirated from the pericardium and about 10 cc. more of the solution was introduced. Five minutes later, when the fluid was aspirated, it was grossly bloody. In all about 30 cc. of the solution was introduced into the pericardium and about 50 cc. of the solution mixed with blood was withdrawn. The opening in the pericardium was sutured.

There were no significant observations until May 31, when a systolic murmur was heard over the right side of the chest. A few days later a pleural effusion and ascites were noticed with swelling of the scrotum and the paws of the hind legs. There was no edema of the forepaws. A roentgenogram showed an increase in the size of the cardiopericardial shadow and an adhesion extending to the right thoracic wall.

July 5: The dog was killed. There was 500 cc. of straw-colored fluid in the thorax, and the abdomen contained several liters of similar fluid. The subcutaneous tissue over the chest, abdomen and hind legs was edematous, but over the neck and forelegs there was no edema. An extensive adhesion between the pericardium, the right lung and the right thoracic wall was found which probably obstructed the inferior vena cava. The pericardium was extensively adherent to the heart and the pericardial cavity was obliterated (fig. 2). A layer of gelatinous exudate was present over the heart posteriorly. The lungs showed slight edema. The liver was congested.

EXPERIMENT 8 (dog 92): The dog weighed 15 Kg. May 10, 1928: An opening about 5 mm. long was made in the pericardium and a soft rubber catheter was inserted into the pericardial cavity. Through the catheter small quantities of surgical solution of chlorinated soda were introduced into the pericardial cavity. The pericardial fluid immediately became turbid, the pulse rate increased and within two minutes the solution was grossly bloody. About 40 cc. of the solution was used, and the irrigation lasted about five minutes. The pericardial cavity was then irrigated with saline solution and the opening in the pericardium was sutured.

Following the operation, the dog was in good condition. On the fourth day a systolic murmur became audible, and a roentgenogram showed an increase in the

Fig. 2 (experiments 6 to 8).—Showing the effect of small quantities of surgical solution of chlorinated soda injected into the pericardial cavity

size of the cardiopericardial shadow. On June 11, the dog sustained a shower of emboli into the lungs. Blood escaped from the mouth. The dog was killed. There was no free fluid in the thorax. About a dozen triangular areas of consolidation were found in the lungs. Each of these extended to the periphery of the lung, and on section, they were found to contain fresh blood. The bronchi and trachea also contained fresh foamy blood. A generalized pericarditis was present with fibrous adhesions. At the base of the heart posteriorly, a shaggy pericarditis was present, and the adhesions were fibrinous and granular. There was a little blood-stained fluid walled off in small pockets. The pericardium was thickened (fig. 2). The abdominal organs were normal. No source of the emboli was found, and it was concluded that probably they arose from the vessels of the pericardium.

*Comment.*—Small quantities of surgical solution of chlorinated soda injected into the normal pericardial cavity usually produced an immediate increase in the pulse rate. Within a few minutes after the injection hemorrhage usually occurred, and this was due to erosion of small blood vessels. The injection of small quantities (40 cc.) of the solution into the pericardial cavity or the irrigation of the pericardial cavity with the solution and then physiologic solution of sodium chloride produced uniformly, within several weeks, a marked reaction consisting of either pericarditis with effusion or pericarditis with adhesions. Generalized edema and polyserositis developed in several experiments, and in one multiple pulmonary infarcts occurred. These observations are especially noteworthy in that the experiments were not complicated by the presence of infection.

*SERIES 3.—Effect of surgical solution of chlorinated soda on the infected pericardium.*

Purulent pericarditis was produced by doing a pericardiostomy and then either letting the pericardium become infected from the exterior or inoculating the pericardium with organisms. Pericardiostomy was effected in two stages. First, the pericardium was sutured securely to the thoracic wall so that the pleural space was completely closed off. As a further precaution against pneumothorax, the muscles and skin of the thoracic wall were sutured and the wound completely closed. At a later date this scar was incised and the pericardium having become adherent to the thoracic wall was opened. If pericardiostomy was carried out in one-stage, pneumothorax or empyema or both frequently complicated the experiment.

EXPERIMENT 9 (dog 12): The dog weighed 20.5 Kg. Oct. 15, 1925: About 3 inches (7.6 cm.) of the fifth rib on the left was resected subperiosteally. The pericardium was sutured with interrupted silk sutures to the parietal pleura over an area almost 3 cm. in diameter, and the muscles of the thoracic wall were approximated over this. The skin was closed with a subcuticular suture.

December 8, 1928: The healed scar was incised and the pericardium was opened without opening the pleura. A small catheter was inserted into the pericardium and left in place. A sterile dressing was applied to the wound.

December 12: A cloudy fluid with a sour odor containing white curdlike flakes drained from the pericardium. Cultures of this fluid showed a nonhemolytic streptococcus. Irrigation through the catheter with 20 cc. of surgical solution of chlorinated soda twice daily was begun.

December 21: The dog had been losing weight and was apparently ill. It was killed by chloroform narcosis. The abdomen contained 1,000 cc. of clear fluid and each pleural space about 500 cc. The lungs showed no consolidation. The pericardium was greatly thickened and adherent in places to the heart. The surface of the heart and pericardium was roughened with wartlike excrescences (fig. 3). The various lobes of the liver were separated from one another by a fibrinous coating which could be easily pulled away.

EXPERIMENT 10 (dog 119): The dog weighed 13 Kg. June 8, 1928: About 7 cm. of the left fourth and fifth ribs were resected subperiosteally. The pericardium was sutured to the wound in the thorax with many interrupted silk sutures so that the pleural space was closed off. The muscle and skin were approximated over the pericardium.

July 11: An incision was made over the scar of the operation and the pericardium was opened without entering the pleura. The incised margin of the pericardium was sutured to the skin. A large sterile dressing was applied.

July 26: The dog was in good general condition. Free pus was exuding from the opening in the pericardium. The pericardium was irrigated with 200 cc. of surgical solution of chlorinated soda. There was no bleeding, no evidence of pain and no change in the pulse rate.

August 3: Irrigation of the pericardial cavity with 200 cc. of the solution was carried out daily. The fluid returned slightly bloody during the last two irrigations. The dog was developing ascites.

August 5: The dog died. At necropsy 1,000 cc. of blood-tinged fluid was in the abdomen and about 400 cc. in each pleural space. The pericardium was thick and fibrous. It was not adherent to the heart except posteriorly where the two structures were firmly grown together (fig. 3). There was no fluid in the pericardium. The surface was shaggy and infected. The lungs were somewhat edematous and the liver was congested.

EXPERIMENT 11 (dog 25): The dog weighed 13.5 Kg. Sept. 8, 1928: About 8 cm. of the left fourth rib was removed. The pericardium was attached to the thoracic wall with interrupted sutures in a circle about 4 cm. in diameter. The pericardium was then opened and the incised edge was sutured to the intercostal muscles so that the pleural space was closed. The subcutaneous fat and the skin were approximated.

September 26: The scar of the operation was incised and the pericardium was opened without entering the pleura. Two cubic centimeters of a broth culture of *Staphylococcus aureus* was injected into the pericardium.

October 9: The pericardial cavity was purulent. Irrigations of the pericardium with surgical solution of chlorinated soda, 15 cc. three times a day, were begun. There was no change in the pulse rate, no bleeding and no signs of pain accompanying the irrigations.

October 17: The dog contracted mange, was losing weight and was killed. There was no fluid in the abdomen or chest, nor any signs of edema or decomposition. The opening in the pericardium was about 1 cm. in diameter. The pericardium was thickened and everywhere adherent to the heart (fig. 3). In places, a shaggy exudate was present.

EXPERIMENT 12 (dog 26): The dog weighed 16 Kg. Sept. 11, 1928: A procedure similar to that of the preceding experiment was carried out.

Fig. 3 (experiments 9 to 12).—Showing specimens of purulent pericarditis in which irrigation of the pericardial cavity with surgical solution of chlorinated soda had been carried out.

September 26: The pericardium was opened as described in experiment 11, and 2 cc. of a broth culture of *Staphylococcus aureus* was injected into it. The dog was in good condition.

October 9: Irrigation of the pericardial cavity with 15 cc. of surgical solution of chlorinated soda three times daily was begun. There was no hemorrhage accompanying the irrigations and no change in the pulse rate.

October 17: The dog was in good condition; it was killed for the specimen. The liver and spleen were a little enlarged; there was no fluid in the abdomen or chest. The lungs were normal. The heart and pericardium were markedly enlarged. A shaggy exudate lay between the heart and pericardium, and in places these structures were bound together by friable adhesions (fig. 3).

*Comment.*—Only a few of the attempts to produce purulent pericarditis are recorded. Many of the experiments were complicated by empyema or pneumothorax. A few were conducted as controls, i.e., purulent pericarditis was produced, but the pericardial cavity was not irrigated with surgical solution of chlorinated soda.

From the experiments recorded, it may be stated that the infected pericardium did not bleed when irrigated with surgical solution of chlorinated soda and the irrigations apparently were not painful. These observations are in agreement with those of Pool and others who used it in the treatment of human cases. The absence of hemorrhage and pain was due, undoubtedly, to the layer of fibrin which in cases of infection protected the pericardium from the erosive action of the solution. The result in each experiment in which purulent pericarditis was produced, whether irrigated with surgical solution of chlorinated soda or not irrigated, was uniformly an extensive generalized pericarditis. Whether there was any difference in the extent of the reaction in these experiments compared with the control experiments cannot be stated. In each, the pericardium was greatly thickened and the adhesions to the heart were extensive. Polyserositis developed frequently in the experiments in which the pericardium was irrigated as it did in the case reported by Pool.

#### CONCLUSIONS

1. Surgical solution of chlorinated soda injected into the normal pericardial cavity of the dog produced a profound reaction. The immediate reaction consisted of pain and hemorrhage. The latter was due to erosion of blood vessels. The end-result of 40 cc. of the solution injected into the normal pericardial cavity was pericarditis with effusion or generalized adhesive pericarditis. Polyserositis and death sometimes resulted.

2. Purulent pericarditis was produced by allowing the pericardium to become infected after a pericardiostomy had been carried out. Irrigation of the infected pericardial cavity with surgical solution of chlorinated soda was not painful and did not produce bleeding. The absence

of pain and hemorrhage was due, presumably, to the protective coating of fibrin which was present on the surface of the pericardium. In each experiment in which purulent pericarditis was produced the end-result was a marked adhesive pericarditis, and this seemed to develop similarly in the experiments in which the pericardial cavity was irrigated with surgical solution of chlorinated soda and in those in which it was not irrigated.

3. The infected pericardium did not react to surgical solution of chlorinated soda as did the normal pericardium. In purulent pericarditis the fibrinous exudate must play an important part in protecting the pericardial surface from the effects of the free chlorine. In the treatment of purulent pericarditis the solution, if used at all, should be used only in carefully selected cases and with great caution. Because of its erosive action it should not be allowed to collect in the pericardial cavity, and an adequate drainage tract is indispensable.

# ARTERIOVENOUS FISTULA: DILATATION OF THE ARTERY DISTAL TO THE ABNORMAL COMMUNICATION

AN UNUSUAL FEATURE EXPERIMENTALLY EXPLAINED\*

EMILE HOLMAN

Since the original description of an arteriovenous aneurysm by William Hunter,<sup>1</sup> innumerable articles have appeared indicating the fascination which this comparatively rare lesion presents both to internists and to surgeons. This fascination has its origin in certain characteristics which are wholly peculiar to this lesion, but which may, in spite of their unique character, aid in a more complete understanding of the phenomena attending other diseases of the circulation.

Objectively, the most striking, though not invariable, phenomenon attending an abnormal communication between an artery and its accompanying vein is a gradual dilatation of the heart and of the blood vessels proximal to the fistula. This dilatation of the heart may be so great as to end in complete cardiac decompensation, as recorded by Reid<sup>2</sup> and Leriche,<sup>3</sup> or it may be entirely absent. The dilatation is due to the distending force of the increased bulk of blood attracted to that part of the circulatory bed represented by the heart, proximal artery, fistula and proximal vein. Just as flowing water seeks the line of least resistance, so this shorter circuit attracts blood to it because of the lessened peripheral resistance offered by the fistula when compared with the resistance offered by the capillary bed elsewhere in the body. This diversion of blood through the shorter circuit greatly increases the cardiac output,<sup>4</sup> the extent of the increase being entirely dependent on the size of the fistula. A small fistula may have no demonstrable effect either on the size of the heart or on the proximal vessels, whereas a large fistula unaccompanied by obstruction to the venous return to

the heart invariably produces a dilatation of the heart and the proximal vessels.<sup>5</sup>

The factor compensating for the diversion of blood from the general circulation into the shorter circuit is an increase in total blood volume.<sup>6</sup> This increase is commensurate with the amount of blood diverted through the fistula, and the amount of blood so diverted determines the increase in the size of the circulatory bed through which the shortcircuited blood flows.

Careful clinical histories have demonstrated in certain instances the slowly progressive character of the cardiac dilatation and disability which accompany an arteriovenous fistula. In three of my cases the fistulas had been present twenty-four, twenty-five and twenty-six years, respectively, with signs of cardiac disability of only a few years' duration. It is my opinion that when this progressive dilatation of the heart and vessels proximal to the fistula occurs, it is accompanied by, and is probably dependent on, a progressive dilatation and widening of the fistula itself. Under such conditions there is present a vicious circle, consisting of a progressive diminution in peripheral resistance due to this progressive dilatation of the fistula, a progressive increase in total blood volume paralleling the amount of blood diverted into the shorter circuit and a progressive dilatation of that part of the circulatory bed comprising the shorter circuit, namely, the heart, proximal artery, fistula and proximal vein.

The crucial factor underlying the progressive dilatation of this part of the circulatory system is the difference in the peripheral resistances offered to the flow of blood (1) by the normal capillary bed in the general circulation and (2) by the fistula in the shorter circuit. The dilatation of this shorter circuit will continue so long as blood will find its way more easily through the fistula than through the capillary bed; in other words, the dilatation will continue until the resistance offered by the surrounding tissues to any further dilatation either of the artery or the fistula, plus the resistance to the flow of blood through the fistula, equals the resistance to the flow of blood offered by the capillary bed elsewhere. When this equalization of resistances is reached, there will be no further increase in the volume of blood flowing toward and through the fistula, and consequently that part of the circulatory system through which this shortcircuited blood must pass will not undergo further dilatation.

The measured diameters of the fistulas in the three cases already mentioned are indicative of a progressive increase in the size of the

fistula. In the first case,<sup>7</sup> a fistula between the popliteal vessels had a measured diameter of 2.1 cm.—a diameter far above the original diameter of the popliteal artery. In the second case,<sup>8</sup> a fistula between the femoral vessels measured 1.8 cm. in diameter, also considerably in excess of the original size of the artery and probably also greater than the original size of the fistula. In the third case,<sup>9</sup> the fistula between the superficial femoral vessels measured 1.4 cm. in diameter. In each of these instances, the artery proximal to the fistula had a diameter over twice that of the corresponding artery in the opposite limb.

Remarkable as is this dilatation of the artery proximal to an arteriovenous fistula, it is an even more arresting fact that on several rare occasions a definite dilatation of the artery distal to the fistula has been recorded. This phenomenon has been particularly puzzling to students of this lesion, and at first glance such a dilatation would appear to be improbable. On further reflection, however, it becomes apparent that under certain conditions this distal dilatation is inevitable. In the healing that occurs following the injury to the two vessels, the arterial wall proximal to the fistula may become rigid due to the deposition of fibrous tissue, or the lumen may even be constricted and partially shut off by the contraction of the fibrous tissue laid down in the reparative process. If the fistulous opening distal to the constriction remains, there would still be an area of diminished resistance in the arterial tree which would have the effect of attracting a large quantity of blood to the fistula, the only avenue of approach being by way of the collateral circulation. An increased volume of blood flowing through the collateral circulation and into the distal artery would, if the fistula were large, inevitably lead to a dilatation of the artery distal to the fistula, just as in other instances the increased bulk of blood flowing through the proximal artery has distended and dilated it.

#### REPORT OF CASES

The following clinical cases illustrate this possibility:

CASE 1 (Breschet<sup>10</sup>).—L. F., aged 22, was injured in the left arm by a sharp instrument which penetrated the artery and vein on the medial superior aspect of the left arm. Six weeks after the accident, he noticed an extraordinary pulsation and "roaring" in the area of the healed wound. Within the next two years, a

8. Holman, Emile: Arteriovenous Aneurism: Clinical Evidence Correlating Size of Fistula with Changes in the Heart and Proximal Vessels, *Ann. Surg.* **80**: 801, 1924.

9. Holman, Emile: Report of Three Cases of Arteriovenous Aneurysm, *S. Clin. N. Amer.*, to be published.

10. Breschet: Mémoire sur les aneurysmes, *Mem. Acad. roy. de méd.* **3**:223, 1833.

large sized pulsating tumor appeared at the same site. The roaring disappeared on compression of the artery proximal to the tumor. Ligation of the artery, according to the method of Hunter (proximal to the tumor), was performed with complete and immediate cessation of the pulsation and roaring. Shortly after the operation, the arm became cold and insensible and the fingers became flexed. On the fourth day a slight hemorrhage occurred, and on the thirteenth day the ligature fell away. Soon a slight murmur was heard at the site of the old tumor which gradually increased. The hand and fingers became markedly flexed. The reappearance of the tumor with all the previous symptoms and the marked dilatation of all the veins indicated a return of the lesion of the artery by the entrance of blood into the vessels situated below the lesion of the artery and principally into the inferior end of the artery which was considerably dilated.

This case illustrates, by the development of an ischemic paralysis, the danger of ligation of the artery proximal to the fistula. That gangrene did not occur was dependent on the prompt development of a collateral circulation sufficient to produce eventually a dilatation of the artery distal to the fistula.

CASE 2 (Breschet<sup>10</sup>).—B. D., aged 22, received an injury on Oct. 26, 1825, from a paring knife which entered his left thigh in Hunter's canal. At the end of three days, the dressing to control hemorrhage was removed and he noted a thrill and bruit in the region of the wound. He entered the hospital on April 27, 1826, with the left lower leg larger than the right; the veins of the leg dilated and varicose; two small ulcerations on the left thigh; a pulsating tumor the size of a nut with a remarkable continuous thrill, which was accentuated in systole and which disappeared on compressing the artery above, and which was augmented on compressing the artery below the tumor. At the operation on May 17, two ligatures were applied proximal to the pulsating tumor. The patient died eight days later following development of gangrene in the leg below the ligature. Examination of the limb revealed a marked dilatation of all the veins of the lower limb. The arteries were injected, and it was found that the arteries even up to the capillary vessels were greatly dilated and tortuous. This dilatation affected not only the trunk of the femoral, the popliteal, and the tibial, but also the peroneal artery and all the smaller branches. At the point corresponding to the injury there was a communication, "large and free," between the artery and vein.

CASE 3 (Cauchois<sup>11</sup>).—A reservist was wounded in the battle of the Marne in August, 1914, by a bullet traversing the popliteal space. Prompt healing of the wound occurred, but it was followed by the appearance of a continuous thrill and bruit indicating the presence of an arteriovenous communication. At the operation on Jan. 20, 1918, the popliteal vein was doubled in size, but the popliteal artery was greatly reduced in volume. The arteriovenous fistula, about 1 cm. long, was situated in the most distal part of the popliteal vessels. A quadruple ligation was performed, and the aneurysmal sac excised. This revealed an anterior tibial artery (distal to the opening) to be wide open, gaping and voluminous in size. Gangrene did not occur due to a remarkable collateral circulation.

11. Cauchois: Anéurisme artérioveneux de la terminaison des vaisseaux poplites, Bull et mém. Soc. de chir. de Paris 41:757, 1915.

CASE 4 (Reid<sup>12</sup>).—A man, aged 35, was admitted to the Johns Hopkins Hospital on Oct. 14, 1921, with an arteriovenous fistula between the left subclavian vessels, caused by a gunshot wound received five months previously. The left radial pulse was small, but palpable. The systolic blood pressure in the right arm was 120 mm. of mercury, in the left, 60; the diastolic pressure was 60 in the right arm and not measurable in the left. At operation, the fistula, which was between the subclavian vessels in their third portion, was excised. Contrary to the usual observations, the artery in this instance was larger on the distal side than on the proximal side of the fistula.

CASE 5 (Reid<sup>12</sup>).—A man, aged 41, was admitted to the Cincinnati General Hospital on May 29, 1922. He had been shot below the left clavicle six months previously. A loud noise and the unmistakable signs of an arteriovenous fistula were detected on the day of the accident. The radial pulse had been good ever since the accident. The pulse rate was 70. The blood pressure in the left arm was systolic, 105; diastolic, 80. In the right arm it was systolic, 120; diastolic, 85. At operation, the fistula was found to be in the third portion of the subclavian artery. The fistulous connection was ligated with silk. The artery distal to the fistula was a little larger than it was on the proximal side. After the operation the blood pressure was the same in both arms, namely, systolic, 120; diastolic, 85.

Experimentally, dilatation of the artery distal to a fistula may be easily produced. Two and one-half years ago, experiments were undertaken to determine the effect of ligating the artery proximal to a previously produced fistula. It was believed that such a procedure would result in evidences of impaired nutrition to the limb comparable to that seen in the clinical cases following ligation of the artery proximal to a fistula. Somewhat to my surprise, no difficulties of nutrition appeared, a fact undoubtedly due to the abundant collateral circulation available in the dog where trifurcation of the aorta occurs in place of bifurcation as in the human being. It was noted that accompanying this remarkable collateral circulation there had occurred also a dilatation of the artery distal to the fistula. A review of the literature then revealed the two clinical observations by Breschet which were exactly comparable to the conditions present in the experimental animals.

The following protocols are presented as illustrative of the experiments which demonstrated the truth of the rare clinical observation that the artery may be dilated distal to a fistula instead of immediately proximal to it.

#### PROTOCOLS

EXPERIMENT 1.—*Dog T1*.—A large, male mongrel, weighing 41 pounds (18.6 Kg.), was used for the experiment. On April 8, 1926, a fistula 2 cm. long was

established between the left femoral artery and vein, the diameters of which measured 4 and 7 mm., respectively. The pulse rate was 90 before the operation, 140 before the opening of the fistula, 148 immediately after it was opened and 165 at the end of the operation.

On April 21, a well marked thrill and bruit were present at the site of the fistula; the left leg was swollen and edematous beyond the fistula, and the superficial veins were unusually prominent. The pulse rate was 120 with the fistula open, and 112 when the fistula was closed by digital pressure. The toes on the left foot were bluer than those on the right, and the left foot was colder than the right.

On this day, the femoral artery proximal to the fistula was exposed and ligated with silk, resulting in an immediate cessation of the thrill and bruit. Four hours later it was noted that the pulse rate had dropped from 120 to 80, the thrill was still absent, and the foot was warmer and pinker than before ligation of the proximal artery. At no time was there any evidence of impaired circulation beyond the fistula. This was contrary to the expected theoretical result.

By April 28, a definite though slight thrill had returned at the site of the fistula, illustrating the ineffectiveness of ligation of the proximal artery in curing a fistula.

On April 30, a fistula 2 cm. long was established between the right femoral artery and the vein. These measured 4 and 6 mm. in diameter, respectively. Within four days, the right leg became enormously swollen, the right thigh measuring 43 cm., the left thigh 33 cm. in circumference. The swelling gradually subsided.

The behavior of the blood pressure beyond the fistula on the left presented some interesting observations. On April 21, after the artery proximal to the fistula had been ligated, blood pressure readings could not be obtained beyond the fistula with a Pachon oscillometer. On June 4, readings could not be obtained on the left, but by August 30, the blood pressure readings were 100 systolic; 20 diastolic. On June 4, the readings on the right below the fistula were 80 systolic; 20 diastolic. On August 30, these were 130 systolic; 30 diastolic. On this date also, the pulse rate was 160 with both fistulas open, and 140 with both fistulas closed.

There then occurred a gradual diminution in the intensity of the thrill and bruit on the right, and by December 8 they had entirely disappeared, indicating the complete closure of the fistula, probably by thrombosis. The thrill and bruit on the left were still intense, and there was a remarkable pulsation visible and palpable in the artery beyond the fistula. The blood pressure in the right leg below the site of the previous fistula was 120 systolic; 55 diastolic. On the left below the still patent fistula, the blood pressure readings were 100 systolic; 55 diastolic.

On May 31, 1927, the dog was killed. Before death, an intense thrill and bruit were present over the left thigh, with marked prominence of the superficial veins and with a prominently beating artery on the distal side of the patent fistula on the left as compared to only a small artery on the distal side of the closed fistula on the right. The pulse rate was 90 with the fistula on the left open, and 72 with it closed.

The vessels were exposed and it was found that the artery distal to the open fistula on the left had a diameter of 7 mm., whereas the artery on the right at a corresponding point was only 4 mm. in diameter. The fistula on the right was occluded by a thrombus, whereas the fistula on the left was widely patent, measuring 0.7 by 1 cm. The artery proximal to the fistula on the left was completely obliterated by fibrosis at the site of the previously applied ligature.

The vessels were injected with bismuth oxychloride (17 per cent solution in 10 per cent gum acacia (fig. 1). The extraordinary dilatation of the collateral

vessels on the left was obvious as compared to the vessels beyond the closed fistula on the right. The increase in the caliber of the anastomotic channels on the left side was also apparent. An interesting observation was the fact that both on dissection of the specimen and in the roentgenograms of the injected specimen the artery distal to the fistula on the left was dilated only in that portion receiving blood from the enlarged collateral bed, i. e., the dilatation extended to about the level of the knee joint. Beyond the knee, the arteries on the two sides were identical in size.

EXPERIMENT 2.—*Dog T8*.—A large, male collie, weighing 32 pounds (14.5 Kg.), was used for this experiment. On April 21, 1927, a fistula 2.6 cm. long was

Fig. 1 (experiment 1, dog T1).—Right femoral fistula established thirteen months previously which closed spontaneously. There is some evidence, however, of a slight increase in collateral circulation as compared to normal leg (fig. 7). A femoral fistula is established on the left at  $F$ , and the proximal artery ligated, resulting in a remarkable development of the anastomotic circulation. Note the dilatation of the artery  $FA^1$  distal to the fistula as compared to artery  $FA^2$  on the right. Note the comparative sizes of the corresponding muscular branches  $M^1$ ,  $M^2$ , and  $N^1$ ,  $N^2$ .

established between the femoral vessels on the right. The artery measured 4 mm. in diameter, the vein 7 mm. A well marked thrill and bruit were present after the operation. On May 3, the vessels proximal to the fistula were exposed and the artery ligated, followed by immediate and complete cessation of the thrill and

bruit at the site of the fistula. After twenty-four hours, a very faint bruit was again heard. This bruit gradually increased, and by June 29, it was as loud as before ligation of the proximal artery. On Jan. 5, 1928, the pulse rate was 92 with the fistula open and 60 with it closed. The artery distal to the fistula on the right was prominent as compared to the artery on the left, and the intense bruit and thrill at the fistula could be made to disappear completely by closing this distal artery.

The animal was killed on January 13, and the abdominal aorta was injected following complete isolation of the fistula to prevent the escape of the injection mass into the veins. Again a remarkable collateral arterial bed was demonstrated (fig. 2) and the artery distal to the fistula measured 5 mm. in diameter, whereas at a corresponding point the left artery measured only 3 mm.

Roentgenograms of the heart (fig. 3) showed a definite diminution in the size of the heart immediately after the establishment of the fistula, whereas a

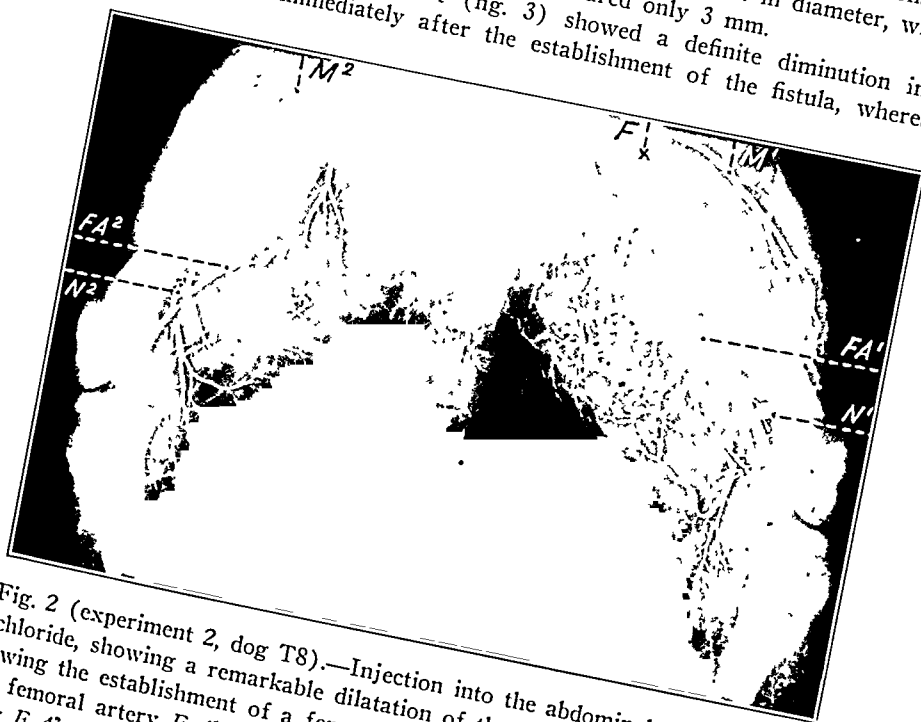

Fig. 2 (experiment 2, dog T8).—Injection into the abdominal aorta of bismuth oxychloride, showing a remarkable dilatation of the collateral vessels nine months following the establishment of a femoral fistula at *F*. Note the dilatation of the main femoral artery *FA'* beyond the fistula as compared to the normal femoral artery *FA'* on the other side. Note also the dilatation of the muscular branches *M'* and *N'* as compared to the corresponding arteries *M'* and *N'* on the normal side.

roentgenogram taken nine months later showed a definite dilatation, in spite of the ligation of the artery proximal to the fistula. This phenomenon of diminution in the size of the artery immediately after the establishment of the fistula followed by dilatation was noted also in animal T10 (fig. 7). The diminution of the size of the heart is due to the diversion of a considerable volume of blood from the arterial side into the venous system directly through the fistula, producing thereby a marked temporary fall in general blood pressure. The fact that after nine months a dilated heart had developed indicates that a considerable volume of blood was finding its way through the collateral circulation and fistula back to the heart.

EXPERIMENT 3.—*Dog T10*.—A large, male police dog, weighing 55 pounds (24.9 Kg.), was used for this experiment. On July 21, 1927, a fistula 2.5 cm. long was established between the right femoral vessels. The artery measured 4 mm. in diameter, the vein 6 mm. On the following day, the right thigh and leg were hugely swollen with a violet discoloration of the skin on the inner aspect of the thigh (fig. 4). By July 28, a large sloughing area had developed at the site of the previously discolored skin. This gradually healed. In this animal, the artery proximal to the fistula was not ligated, in order to observe the effects of a simple fistula on the development of the collateral circulation.

On Jan. 3, 1928, it was noted that an artery could not be felt distal to the fistula, whereas in the other animals, in which the artery proximal to the fistula

Fig. 3 (experiment 2, dog T8).—Roentgenogram of normal heart is shown in *a*; *b*, roentgenogram immediately after establishment of left femoral fistula showing diminution in size of heart; *c*, roentgenogram nine months later showing dilatation of the heart. In this instance, the artery proximal to the fistula was ligated twelve days after the production of the fistula so that the blood reached the fistula by way of the collateral circulation and distal artery.

was ligated, there had developed a prominent artery distal to the fistula. The pulse rate on this date was 104 with the fistula open, and 96 with it closed.

On August 16, the animal was killed and the aorta injected with bismuth oxychloride. Roentgenograms were obtained (1) with the right femoral artery open proximal and distal to the fistula, but with the vein ligated proximal and distal to the fistula; left artery and vein open (fig. 5), and (2) with both artery

Fig. 4 (experiment 3, dog T10) —Marked edema twenty-four hours after the establishment of a large right femoral fistula at *F* is shown in *a*; *b*, seven days later showing patch of necrosis at *G* due to impaired circulation distal to fistula; *c*, twelve months later showing permanent enlargement of thigh on side of fistula.

Fig 5 (experiment 3, dog T10) —Injection into the abdominal aorta with the vein ligated distal and proximal to fistula at *F*. The femoral fistula was established on the right thirteen months previously. There is definite dilatation of the artery proximal to the fistula, but no dilatation distal to the fistula. There is a definite dilatation of the anastomotic circulation as compared to the normal left leg, but less marked when compared with the collateral circulation which develops when the proximal artery has been ligated as in figures 1 and 2.

and vein open permitting the injection mass to flow directly into the venous system through the fistula (fig. 6).

From the roentgenograms and from observations made during dissection, it was apparent that demonstrable dilatation of the artery had not occurred distal to the fistula, although a definite increase in collateral circulation had developed. This development of the collateral circulation, however, was only of a mild degree as compared to the remarkable development of collateral circulation when the fistula is widely open, and when the blood flowing through it is coming only from the distal artery, the proximal artery having been ligated. The artery proximal to the fistula measured 6 mm. on the right as compared to a diameter of 4 mm. before the establishment of the fistula; the artery on the left at a corresponding

Fig. 6 (experiment 3, dog T10).—Injection into the abdominal aorta with femoral fistula on right open, permitting the opaque mass to enter directly into the veins. Note the enormous venous bed in the right thigh capable of holding a large volume of blood.

point had only a diameter of 4 mm. The roentgenograms of the heart (fig. 7) again showed diminution in its size immediately after the establishment of the fistula, and considerable dilatation thirteen months later.

This phenomenon of dilatation of the artery distal to a fistula due to the development of an extraordinary collateral circulation is of particular interest because of its bearing on the question of collateral circulation in general. Reid<sup>12</sup> has called attention to the fistula as a most powerful stimulus to the development of collateral circulation.

But he adds: "When we consider that the parts peripheral to a fistula are deprived of their allotted blood supply by reason of a shunt, there is little wonder that nature makes a prodigious effort to compensate by the development of other vascular channels." It appears to me that the "need of the tissues" beyond the fistula has little to do with the development of the collateral circulation. The important fact is the presence of an area of lessened resistance to the flow of blood at the site of the fistula. It is this area of lessened resistance in the arterial tree that attracts blood to this site through all available channels including the

Fig. 7 (experiment 3, T10).—Roentgenograms of heart (*a*) before the establishment of a right femoral fistula; *b*, immediately after the production of the fistula showing definite diminution; *c*, thirteen months later showing marked increase in size of heart.

collateral vessels. That this is true is proved by the experiments in which a constriction of the artery proximal to the fistula was produced, and it is probably equally true if the abnormal opening is large with no constriction of the proximal artery. Under such circumstances, the volume of blood which may pass through the fistula is larger than the volume which can be supplied by the proximal artery alone. The cross-section of the fistula is larger than the cross-section of the proximal

artery, and since the column of blood which may pass through the fistula exceeds in size the column of blood coming through the proximal artery, the collateral circulatory bed opens up its channels to pour an additional volume of blood into the fistula. All avenues of approach to the fistula open up to appease, as it were, the thirst of the fistula.

The important factor in the opening up of the collateral bed in the presence of an arteriovenous fistula is, therefore, not the need of the distal tissues but the presence of a large opening in the artery through which blood may flow without encountering the resistance presented everywhere else in the body by the capillary bed.

Similarly, the opening up of a collateral circulation following an obstruction to the flow of blood through the main artery by tumor or by ligation may be explained on the basis of an area of lessened peripheral resistance more satisfactorily than on the basis of the need of the tissues.

Fig. 8.—Diagrammatic presentation (*a*) of circulatory bed in the presence of a large femoral fistula, the main current of blood entering the fistula by way of the proximal artery, which is dilated; *b*, diagrammatic presentation of circulatory bed in the presence of a large femoral fistula, the main current of blood reaching the fistula by way of the collateral circulation and distal artery, the proximal artery having been ligated.

There is a "great need" for blood in those tissues which lie beyond the gradual occlusion of the arterial tree through arteriosclerosis or endarteritis, but under these circumstances little collateral circulation has been observed. When there is a localized occlusion of a large artery as by a tumor or by ligation, there remains a large arterial bed or lake, distal to the occlusion, which is capable of holding a considerable volume of blood, and which, therefore, presents a lessened resistance to flowing blood than the capillary bed elsewhere. As a consequence, there is an opening up of the collateral bed to pour blood into this large arterial bed or lake beyond the obstruction. If this opening up of the collateral vessels proceeds quickly enough to fill adequately this distal arterial

bed, gangrene will be averted. But if the collateral vessels are small or few in number, the filling of the distal bed occurs too slowly or too inadequately and gangrene is inevitable.

One may contend that once this arterial lake beyond the obstruction is filled, there is no longer an area of least resistance into which the blood may flow, and that therefore there is no further reason to increase either the size or the number of the collateral vessels. Experience teaches, however, that it is a progressive process. The reason probably lies in the fact that although the arterial lake may be filled, it does not remain so. Muscular activity as well as the natural elasticity of the arterial wall will assist in propelling forward the blood contained in the large arteries distal to the obstruction into the more distant capillary bed. As the blood leaves this arterial bed, more blood flows in through the developing collateral bed. It is suggested that if a deficient blood supply is anticipated following ligation of an artery, the extremity be passively and actively exercised as an aid in the development of the collateral circulation.

#### SUMMARY

1. Dilatation of the heart and of the artery and vein on the proximal side of a peripheral fistula is the usual accompaniment of an arteriovenous fistula if it is sufficiently large and of sufficiently long duration.

2. Evidence is available indicating that in certain instances this dilatation of the heart and vessels may be steadily progressive over a period of years, accompanied by and probably dependent on a progressive dilatation also of the fistula itself.

3. The progressive dilatation of the fistula accompanied by a progressive dilatation of the heart introduces a vicious circle which under certain conditions can end only in complete cardiac decompensation.

4. Experimental evidence is presented to show that the collateral circulation near the fistula may also participate in the dilatation of the circulatory bed through which the shortcircuited blood passes. If the fistula is large, blood will seek the fistula through all available channels including the collateral circulation because of the lowered resistance at the fistula.

5. On rare occasions, there occurs a dilatation of the artery distal to a fistula. The explanation of this dilatation lies in the development of such an extensive collateral circulation that the main current of blood flowing through the fistula is supplied from the artery distal to the abnormal communication.

6. Experimentally, distal dilatation of the artery can be produced by establishing a fistula, and, after a free flow of blood through the fistula has developed, by ligating the artery proximal to the fistula. The area of lessened resistance at the site of the fistula will attract a large volume

of blood through the collateral bed, the blood reaching the fistula through the distal artery which dilates in response to the increased bulk of blood flowing through it.

7. In the clinical cases, the flow through the distal artery and the failure of blood to reach the fistula through the proximal artery is presumably due to fibrous tissue deposited in the course of healing, which constricts the proximal artery or prevents its dilatation.

8. In the experimental animal, dilatation of the heart may occur in the presence of a fistula with the proximal artery ligated, indicating that a considerable volume of blood is being shortcircuited through the fistula, the blood reaching it through the collateral circulation.

9. In the experimental animal, ligation of the artery proximal to a fistula may temporarily obliterate the thrill and bruit of a fistula, but they promptly recur due to the development of an extensive collateral circulation. In clinical cases, ligation of the proximal artery alone is contraindicated because of danger of gangrene and, if gangrene is averted, because failure to cure the fistula invariably follows, as proved experimentally.

# MUSCLE TONE IN DECEREBRATE RIGIDITY\*

LOYAL DAVIS

Tonus is a property of muscle which exists and concerning which much has been written; but a clear definition of muscle tone is not yet available. This lack of definiteness has resulted in controversies over apparently similar, but actually different, properties of muscle. It is not known what relationship exists between tension, elasticity, extensibility, resiliency and tone; yet all these properties of muscle have been spoken of as muscle tonus. Perhaps all these properties constitute tone.

Peculiarly enough, in spite of the lack of an accurate definition, there is a conception among investigators of what is spoken of as muscle tone. Dependent on one's point of view is this conception. Galen spoke of muscle tone as an "active posture." Johannes Müller employed the term to mean a slight contractile tension present in a normal muscle at rest. Sherrington's school believe that it is the result of a proprioceptive reflex and that stretch is the adequate stimulus. Metabolic and physical alterations in the muscles may produce changes in muscle tone without evoking the intervention of the central nervous system in the sense of a stretch reflex. For example, little or nothing is known of the peripheral changes in the muscle which accompany myotonia, tetany, local anemia or diseases of the globus pallidus.

Experimentally, the problem may be reduced to a simple one. However, as successively higher levels are added to the simple spinal reflex arc, the problem becomes more intricate, and the interpretation of results more hazardous. Thus it becomes extremely difficult to analyze muscle tone clinically when one is dealing with the imposing influence of voluntary innervation.

## PATTERN OF DECEREBRATE RIGIDITY

Much of what is known about muscle tone has been learned from the study of decerebrate animals. Pollock and I became involved in the subject through the natural development of our interest in a method of decerebration. In 1896, Sherrington described the condition of decerebrate rigidity which followed transection of the brain stem at any level between the colliculi and the exit of the eighth pair of cranial nerves. Following this work, decerebrate animals were produced by ablation of the cerebrum or by the gross cutting through of the brain stem.

---

\* From the Laboratory of Surgical Research, Northwestern University Medical School.

These mutilating operations were attended by a high mortality, and were associated with a great degree of shock. The exact level of decerebration could not be predetermined, and a complete decerebration was not assured until postmortem examination. Frequently, some part of the brain cephalad to the decerebration remained intact. Bleeding was difficult to control, and the degree of hemorrhage was immeasurable. Shock obscured the picture, and the time of its disappearance could not be determined accurately. An animal decerebrated by such methods showed symptoms which resulted not only because of the removal of function of certain parts of the brain, but also because of compression, which was the result of hemorrhage and mutilation of an immeasurable area of nervous tissue adjacent to the operative wound.

It was shown by Hill that occlusion of the blood supply to the central nervous system for fifteen minutes produces damage from which there can be no recovery. This fact was corroborated by many workers, and Stewart, Guthrie, Burns and Pike produced excellent "spinal" animals by the combined occlusion of the vertebral and carotid arteries. Often, they were obliged to ligate the right innominate and the left subclavian arteries as well. It followed that if a method could be devised whereby anemia of a certain isolated part of the cerebrum could be produced for a period longer than fifteen minutes, that part of the brain would be rendered functionless.

Studies on comparative anatomy have shown that the cerebral arteries are laid down with remarkable precision, and the distribution is associated closely with the function of the parts supplied. According to Stopford, who studied the distribution of the blood vessels to the pons and medulla by means of injection experiments, the nutrient vessels to the pons and medulla are true end-arteries and may be utilized in the investigation of function of certain parts of the medulla and pons. It seemed possible, then, in the absence of anastomotic vessels, to interrupt the continuity of the blood stream in the basilar artery by a ligature, and thus to separate that part caudad from that cephalad to the ligature. If the carotid arteries were then tied, a complete anemia of the brain cephalad to the ligature on the basilar artery was produced. In a former communication, Pollock and I published a description of an operation to produce an anemic decerebrate animal. The method of decerebration by anemia consisted of two steps: (1) the ligation of the basilar artery at any desired level and (2) the ligation of the carotid arteries.

Without exception, after ligation of the carotid and basilar arteries, decerebrate rigidity, so completely described and analyzed by Sherrington and later by Magnus and de Kleijn, ensues. When fully developed, the rigidity is marked, the spine is extended and the tail is held in a horizontal position or is curved strongly upward, at times to the degree of

lying parallel to the back. Any attempt to depress the tail is followed by immediate resumption of its original position. The extremities are fully outstretched; the fore-legs are held stiffly extended at the shoulder and elbow joints and are retracted. The angles between the limbs and the body vary as to the position of the body. If the animal is placed as if sitting on its haunches, the angle is smaller than if the trunk is horizontal. The wrist joints are seldom involved in the rigidity. The hind-legs are thrust backward and are outstretched, but to a lesser degree. All the joints in the hind-legs are equally involved. The head is maintained in a lifted position, despite gravity, and there may be some opisthotonos of the head on the neck. The degree of opisthotonos may be increased by pressure against the outstretched fore-legs or by moving them forward. The jaws are tightly closed. Considerable force is required to produce flexion of the extended extremities, and when released they immediately assume their former position. Numerous reflex reactions may be demonstrated. Such an animal, if carefully posed, can be made to stand. In fact, the posture has been described as rigidity in an antigravity position, or as a caricature of standing.

Former workers were concerned with experimental attempts to abolish this rigidity by section of the eighth cranial nerves and by removal of the cerebellum, red nucleus and other parts of the nervous system which remained intact. They assumed, by the direction of their research, that the entire function of that part of the central nervous system remaining after decerebration was expressed in the resulting rigidity in an antigravity position. On the contrary, Pollock and I felt that the standing reflex of decerebrate rigidity was but one of the simplest patterns which could be released. If other patterns were present, they either were inhibited or could not break through the extreme extensor rigidity which was ordinarily present. Our investigations, therefore, dealt largely with attempts to release other patterns by removal of the remaining parts of the nervous system which either inhibit them or, by selective influence on extensor tone, prevent their appearance. It would follow then that, depending on the level of decerebration and on the influence of other reflex activities present, the pattern of rigidity following decerebration would materially change.

In the decerebrate preparation produced by the ligation of the basilar and carotid arteries, the superior part of the cerebellum is functionless. When the inferior cerebellar arteries are electrocoagulated, tied or severed, the function of the entire cerebellum has been destroyed. If the preparation is made by a ligation of the basilar artery distal to the inferior cerebellar arteries, the cerebellum does not function. In both types of experiments, the pattern and degree of rigidity were the same, and the animals could not be differentiated by their appearance from a good Sherrington preparation.

The pattern of rigidity is dependent undoubtedly on the functional activities of the brain-stem of the particular animal studied. In the decerebrate sloth, which normally hangs from trees, Richter and Bartemeier described lasting flexor rigidity in a pattern of reflex hanging following decerebration. In monkeys, decerebration by the anemic method was characterized by a constantly flexed position of the arm. Extensor rigidity could be produced by suitable stimuli, such as pushing on the passively extended wrist. Occasionally, flexor rigidity has been noted in decerebrate animals by other workers. Bazett and Penfield found that an extensor rigidity might alternate with one of flexion, and that the more chronic the preparation the more tendency there was for a flexed position to appear.

#### INFLUENCE OF THE LABYRINTHS
